Foreword

Worldwide interest in food microbiology has never been greater. Concerns over food safety and quality, as well as food preservation and manufacture, have elevated the importance of food microbiology to an all time high. Consequently, the demand for current and comprehensive information and knowledge about the microbial aspects of food also has risen to new heights.

In response to these needs, the editors, Barbara Lund, Tony Baird-Parker, and Grahame Gould, all internationally recognized leaders in the field, have brought together more than 80 experts in the microbiology of food to address their specific specialities and lend their expertise to understanding the challenges of food safety and quality. This two-volume text serves as an outstanding reference for individuals responsible for the production, processing, distribution, sale, and serving of food; for the control of hazards and spoilage of food products; for teaching or studying the principles of food microbiology; and for assessing and regulating the safety and quality of foods. Its global approach fits well with today's needs.

The essentials of microbiological safety and quality of food have been brought together in this one book and presented in four major sections. Part I includes an introductory chapter, which presents an overview of safe and stable food production. The section then covers fundamental principles and practical information about food preservation. The factors influencing microbial survival and growth are related to processes and methods used to control microorganisms that may be hazardous or degradative or both. The most recent approaches to preservation including emerging nonthermal treatments and predictive modeling are included. Knowledge of the microbial ecology of foods represents a basic approach to the safety and quality of foods. This is addressed in Part II. Experts on the contamination, spoilage, and preservation of specific commodity groups representing all the major categories of food have compiled comprehensive overviews in each of these chapters.

Volume II begins with Part III which covers extensively foodborne pathogens and disease. This section is introduced by a review of the aspect of foodborne disease surveillance including its importance and the limitations and strategy of epidemiological investigations and reporting systems. Then a series of chapters on the major recognized foodborne pathogens, as well as the less well-recognized and unusual foodborne microbial illnesses, is presented. Long-term consequences as well as economic impacts are also important topics that are covered. The comprehensive nature of the chapters is evident in the content that includes the history, the characteristics and pathogenicity of the microorganisms and the disease, general epidemiology and incidence in food, the methods of isolation, and the factors that influence control. Part IV builds upon this extensive foundation and focuses on assurance of microbiological safety and quality. It presents chapters on the preventive approaches of food quality systems including HACCP, on hygienic design of installations, and on the various aspects of sampling and detection of microorganisms in food. The book concludes with a chapter covering the most recent thoughts on risk assessment and microbiological criteria for foods.

This compilation and advice will prove extraordinarily useful to all who are responsible for the microbiological safety and quality of foods. The use of this material, especially with its global approach and the experience of all the authors involved, should serve to enhance the safety and quality of the food offered to the public, wherever they may be.

Preface

Substantial reductions in the incidence of foodborne disease and of food spoilage will only be achieved by applying our existing and developing knowledge and understanding of the biology, physiology, ecology, and pathogenicity of foodborne microorganisms and of traditional, new, and emerging food processing and preservation technologies. There is an urgent need to disseminate this knowledge to those concerned with the production and manufacture of food and to policy makers responsible for food legislation, and to ensure that appropriate intervention policies are promoted and implemented.

There is a wealth of relevant information, which is spread widely through an extensive literature on food science and technology, on medical aspects of foodborne disease, and on general microbiology. In this book we have brought together the key elements of this information that relate to the microbiological safety and quality of food, in chapters written by internationally renowned experts in their particular fields. Our hope is that the comprehensive coverage collected and reviewed critically here will contribute to the evolution of improvements in food safety and quality.

It is our aim that this book will be of value to practicing food microbiologists, persons responsible for development, production, and control in the food industry, and to medical and public health professionals, legislators, and lecturers and advanced students of food microbiology.

We wish to thank all the authors who have contributed chapters to this book for their co-operation, hard work, and patience, and the staff of Aspen Publishers for their enthusiastic help and collaboration.

Barbara M. Lund
Tony C. Baird-Parker
Grahame W. Gould

Foreword ... xxv

Preface ... xxvii

Part I. Principles and Application of Food Preservation Techniques ... 1

1. The Production of Microbiologically Safe and Stable Foods ... 3
   - 1.1 History and Background ... 3
   - 1.2 Sources of Foodborne Pathogenic Microorganisms ... 7
   - 1.3 Control of Foodborne Pathogenic Microorganisms ... 8
   - 1.4 Assessment of Microbiological Risks ... 11
   - 1.5 The Role of Legislation ... 13
   - 1.6 The Future ... 14
   - 1.7 Concluding Remarks ... 16
2. Strategies for Food Preservation ... 19
   - 2.1 Introduction ... 19
   - 2.2 Microbial Targets for Food Preservation ... 21
   - 2.3 Preservation and Shelf Life Extension ... 25
   - 2.4 Combination Preservation Techniques ... 26
   - 2.5 Concluding Remarks ... 31
3. Heat Treatment ... 36
   - 3.1 Introduction ... 36
   - 3.2 Kinetics of Destruction of Microorganisms by Moist Heat ... 38
   - 3.3 Determination of Resistance to Moist Heat ... 43
   - 3.4 Selecting the F_T-Value for Low-Acid Canned Foods ... 46
   - 3.5 Heat Delivery ... 50
   - 3.6 Concluding Remarks ... 60
   - Appendix 3-A: Definitions ... 64
4. Irradiation ... 65
   - 4.1 Introduction and Historical Perspective ... 65
   - 4.2 Irradiation Processing ... 67
   - 4.3 Applications of Food Irradiation ... 68

4.4 Biological Effects 69
4.5 Improvement in Food Safety 74
4.6 Extension of Shelf Life 78
4.7 Combination Treatments 81
4.8 Consumer Concerns 82
4.9 Concluding Remarks 83
Appendix 4-A: Clearance of Item by Country 89
5. Chill Storage 101
5.1 Introduction 101
5.2 Distribution of Psychrophilic and Psychrotrophic Microorganisms in Natural Environments 102
5.3 Effect of Temperature on the Growth of Psychrophiles and Psychrotrophs 103
5.4 Effects of Temperature on Solute Uptake 104
5.5 Effects of Temperature on Membrane Structure and Function 105
5.6 Effect of Temperature on Protein Synthesis and Enzyme Activity 108
5.7 Growth and Survival of Food-Associated Microorganisms at Low Temperatures 109
5.8 Concluding Remarks 116
6. Freezing 122
6.1 Introduction 122
6.2 The Production of Frozen Food 123
6.3 Physical Changes During Freezing 126
6.4 The Effect of Freezing on Microorganisms 128
6.5 Examples of the Effect of Freezing on Microorganisms Associated With Foods 132
6.6 The Microbial Flora of Frozen Foods 136
6.7 Outbreaks of Disease Associated With Frozen Foods 137
6.8 Microbiological Spoilage of Frozen Foods 140
6.9 Concluding Remarks 141
7. Drying and Reduction of Water Activity 146
7.1 Introduction 146
7.2 The Concept of Water Activity 147
7.3 Water Activity and the Water Content of Foods 148
7.4 Water Relations of Microbial Growth 150
7.5 Water Relations of Microbial Death and Survival 154
7.6 Physiological Basis of Tolerance to Low Water Activity 156
7.7 Interactions of α_w with Other Environmental Factors 157
7.8 Specific Solute Effects 158

7.9 Preservation of Foods at Reduced α_w 159
7.10 Determination of Water Activity 165
7.11 Moisture Determination 167
7.12 Concluding Remarks 167

8. Control of pH and Use of Organic Acids 175
8.1 Introduction 175
8.2 The Effect of pH, Acidulants, and Organic Acid Preservatives on Growth of Microorganisms 176
8.3 The Effect of pH, Acidulants, and Organic Acid Preservatives on Survival and Death of Microorganisms 187
8.4 Mechanism of Effect of pH, Acidulants, and Organic Acid Preservatives 192
8.5 Factors Influencing the Effect of pH, Acidulants, and Organic Acid Preservatives 194
8.6 Concluding Remarks 196

9. The Use of Other Chemical Preservatives: Sulfite and Nitrite 200
9.1 Introduction 200
9.2 Sulfite 200
9.3 Nitrite 205
9.4 Concluding Remarks 210

10. Modified Atmospheres 214
10.1 Introduction 214
10.2 The Effect of Oxygen on Microorganisms 215
10.3 The Effect of Carbon Dioxide on Microorganisms 216
10.4 The Use of Modified Atmospheres in Preservation of Fresh Meat 219
10.5 The Use of Modified Atmospheres in Preservation of Fresh Fish 223
10.6 The Use of Modified Atmospheres in Preservation of Processed Meats 226
10.7 The Use of Modified Atmospheres in Preservation of Other Foods 228
10.8 Some Safety Aspects of Modified Atmospheres 228
10.9 Concluding Remarks 229

11. The Effect of Redox Potential 235
11.1 Introduction: Oxidation-Reduction Reactions and Redox Potentials 235
11.2 In Practice: Redox Potentials of Biological Systems 239
11.3 Redox Potentials and Foodstuffs 243
11.4 Concluding Remarks 248

12. Microorganisms and Their Products in the Preservation of Foods 251
12.1 Introduction: Historical Perspective 251
12.2 The Preservation of Foods Involving Traditional Methods of Fermentation 252

12.3 Bacteriocins 258
12.4 Concluding Remarks 268

13. New and Emerging Physical Methods of Preservation 277
13.1 Introduction 277
13.2 High Hydrostatic Pressure 277
13.3 High Voltage Electric Discharge 283
13.4 High-Intensity Light 286
13.5 High-Intensity Magnetic Fields 287
13.6 Manothermosonication 287
13.7 Concluding Remarks 288

14. Use of Combined Preservative Factors in Foods of Developing Countries 294
14.1 Introduction 294
14.2 Principles of Food Preservation in Developing Countries 295
14.3 Recent Applications of Hurdle Technology in Developing Countries 297
14.4 Concluding Remarks 310

15. Injured Bacteria 315
15.1 Introduction 315
15.2 Definitions of Viability, Death, and Sublethal Injury 316
15.3 The Nature of Sublethal Injury 316
15.4 Viable But Nonculturable Cells 321
15.5 Spore Injury 327
15.6 Recovery of Injured Spores 330
15.7 Recovery of Injured Vegetative Cells 331
15.8 The Role of Sublethal Injury in Combined Treatments for Preserving Food 334
15.9 Concluding Remarks 335

16. Principles and Application of Predictive Modeling of the Effects of Preservative Factors on Microorganisms 342
16.1 Introduction 342
16.2 Overview 342
16.3 Modeling Microbial Responses 343
16.4 Computational Aspects of Creating Predictive Models: A New Modeling Approach 347
16.5 Prospects 354

Part II. Microbial Ecology of Different Types of Food 359

17. Fresh Red Meats 361
17.1 Introduction 361
17.2 Composition 364

17.3 Slaughter/Processing 366
17.4 Initial Microflora of Fresh Raw Meats 374
17.5 Effect of Storage and Packaging on the Microflora of Raw Meats 380
17.6 Effect of Cooking 383
17.7 Concluding Remarks 383

18. Processed Meat Products 389
18.1 Introduction 389
18.2 Factors Affecting the Microbiology of Meat Products 390
18.3 Production of Meat Products 395
18.4 Product Types 396
18.5 Concluding Remarks 409

19. Fermented Meats 420
19.1 Introduction 420
19.2 Traditional Types of Fermented Meats and Their Manufacture 420
19.3 Microorganisms Involved in Meat Fermentations, and Factors Affecting them 423
19.4 Microbiological, Chemical, and Physical Changes During Meat Fermentations 425
19.5 Starter Cultures 429
19.6 Application of HACCP to the Production of Fermented Meat Products 431
19.7 Mechanisms and Control of Spoilage of Meats During and After Fermentation 435
19.8 Recent and Future Developments 437

20. Fresh and Further-Processed Poultry 445
20.1 Introduction 445
20.2 Sources of Product Contamination with Human Pathogens and Spoilage Organisms 447
20.3 The Processing Plant 451
20.4 Raw Poultry Products 461
20.5 Further-Processed Products 464
20.6 Concluding Remarks 466

21. Fresh and Processed Fish and Shellfish 472
21.1 Introduction 472
21.2 Chemical Composition of Fish and Shellfish 473
21.3 Microbiology of Freshly Caught Fish and Shellfish 475
21.4 Microbiological Hazards in Fresh Fish and Shellfish 478
21.5 Microbiological Hazards in Fish and Shellfish Products 488
21.6 Concluding Remarks 497

22. Milk and Unfermented Milk Products 507

22.1 Introduction 507
22.2 Milk Composition 508
22.3 Unfermented Products Made from Milk 510
22.4 Microflora of Raw Milk 511
22.5 Natural Antimicrobial Compounds in Raw Milk 518
22.6 Competitive Effects between Microorganisms Found in Milk 519
22.7 Other Methods for Prolonging the Storage Life of Raw Milk 520
22.8 Processing of Raw Milk 521
22.9 Other Methods of Pasteurization of Milk 526
22.10 The Future 527

23. Fermented Milk Products 535

23.1 Historical Introduction 535
23.2 The Substrate Milk 536
23.3 Sources of Microorganisms Used in Dairy Fermentations 537
23.4 Fermented Milk Products 548
23.5 The Bacteriophage Problem in Dairy Fermentation 566
23.6 Fermented Dairy Products Containing "Probiotic" Microorganisms 569
23.7 The Microbiological Safety of Fermented Dairy Products 572
23.8 Concluding Remarks 584

24. Eggs and Egg Products 590

24.1 Introduction 590
24.2 The Formation, Structure and Composition of Eggs 591
24.3 Changes in the Structure and Composition with Time 592
24.4 The Antimicrobial Defense Systems in Eggs 593
24.5 Microbial Infection of Eggs during Passage through the Oviduct 594
24.6 The Microbiology of Rotten Eggs 597
24.7 Course of Microbial Infection of Eggs 599
24.8 Egg Products 606
24.9 The Future 614

25. Fresh and Processed Vegetables 620

25.1 Introduction 620
25.2 The Microbiology of Raw Vegetables 621
25.3 The Microbiology of Fresh Vegetables During Storage 637
25.4 The Effect of Minimal Processing on the Microbiology of Vegetables 639
25.5 Control of Microorganisms on Fresh Vegetables 649

25.6 Microbiology of Processed Vegetables 664
25.7 Concluding Remarks 667
26. Fermented and Acidified Plant Foods 685
26.1 Introduction 685
26.2 Vegetables and Olives 686
26.3 Cereals, Tubers, and Roots (Starchy Plant Foods) 703
26.4 Legumes, Oilseeds, and Treeborne Seeds (Proteinaceous Plant Foods) 718
26.5 Concluding Remarks 732
27. Fresh and Processed Fruits 738
27.1 Introduction 738
27.2 Composition and Properties 738
27.3 Major Groups of Microorganisms Associated with Fresh Fruits 740
27.4 Microbiological Spoilage of Fresh Fruits 740
27.5 Microbiological Safety of Fresh Fruits 743
27.6 Control of Microbiological Spoilage of Fresh Fruits 746
27.7 Control of the Microbiological Safety of Fresh Fruits 748
27.8 Frozen Fruits 750
27.9 Dried Fruits 750
27.10 Canned Fruits 752
27.11 Concluding Remarks 754
28. Cereals and Cereal Products 759
28.1 Introduction – the Importance of Cereals 759
28.2 Microflora on Cereals in the Field 760
28.3 Harvest, Drying, Transport, and Storage 763
28.4 Primary Processing at the Mill 766
28.5 Further Processing 766
28.6 Concluding Remarks 777
29. Yellow Fat Products (Butter, Margarine, Dairy and Nondairy Spreads) 784
29.1 Introduction 784
29.2 Butter 785
29.3 Margarine 792
29.4 Dairy and Nondairy Spreads 798
29.5 Preservation 800
29.6 Concluding Remarks 803
30. Mayonnaise, Dressings, Mustard, Mayonnaise-Based Salads, and Acid Sauces 807
30.1 Introduction 807
30.2 Mayonnaise, Dressings and Other Emulsified Sauces 808

30.3 Ketchup, Vinaigrette and Other Nonemulsified Sauces 820
30.4 Mustard 822
30.5 Mayonnaise-Based Salads 824
30.6 Pasteurized Acid Sauces 828
30.7 Concluding Remarks 830

31. Fruit Juices, Fruit Drinks, and Soft Drinks 836
31.1 Introduction 836
31.2 Composition and Characteristics of Fruit Juices and Soft Drinks 837
31.3 The Microbiology of the Manufacturing Process 841
31.4 Microbial Spoilage of Fruit Juices and Soft Drinks 845
31.5 Preservation and Preservation Procedures 850
31.6 Microbiological Safety: Risks to Human Health 858
31.7 Concluding Remarks and Future Trends 859

1.1 HISTORY AND BACKGROUND

Mankind has learned over many millennia which plant and animal species are edible and how the most useful of these could be cultivated, harvested, and stored to provide a supply of safe and nutritious food throughout the year. The establishment of such a food supply enabled man to progress from being a hunter and gatherer of food (pre-7000 to 8000 B.C.) to become a farmer, food producer, and local trader, and finally to become urbanized and to trade foods with neighboring and distant countries.

During urbanization, it was recognized that certain practices established for the preparation and storage of foodstuffs could lead to food-associated illnesses. Thus, many religious taboos and the early public health acts were concerned with the avoidance of illness from the consumption of foods.[12] For instance, over a thousand years ago, the Byzantine Emperor Leo VI (886–911 A.D.) banned the consumption of blood sausages in order to reduce the high incidence of sausage poisoning (subsequently categorized as botulism) among his people. The law he applied concerning the consumption of blood carried a most severe penalty if it was disobeyed. It stated: "A person found to have prepared blood as food, whether he sells it or buys it, shall have all his property confiscated, and, after having been severely scourged and disgracefully shaved, shall be exiled for life."[36] In England, the Statute of Pillory and Tumbrel (1266–1267) required that "If any butcher do sell contagious flesh or that hath died of the murrain" [any infectious disease of cattle] be punished. The customary punishment was to be placed in the stocks with the offending meat buried under them.[12]

Various authors and bodies have ranked the hazards associated with consumption of foods, and while the order of some vary depending on the region of the world and when the ranking was done, one of the main causes of human morbidity and mortality is microbiological contamination. The most quoted ranking of hazards associated with foodstuffs is by Wodicka[70] who lists the following in order of decreasing importance for Western communities: microbiological contaminants, nutritional deficiencies, environmental contaminants, natural toxicants, pesticide residues, and food additives.

1.1.1 Spoilage

Microbial spoilage of foods is caused by the growth and metabolic activities of various microorganisms. The wide range of microbial associations and metabolites that lead to the spoilage of foods is considered in detail in the food commodity chapters (Chapters 17–36) and some of the main metabolites are listed in Table 1-1.

Although it was not until the mid-19th century that microorganisms were finally shown to cause food spoilage by Louis Pasteur and others, thousands of years before this, man had developed means of preventing spoilage based on the use of empiricism to identify suitable methods. These methods included many of those still used today such as drying, freezing, smoking, curing, and fermenting. The use of these procedures added variety to the diet, and allowed early man to store and to transport otherwise perishable foods, and thus played an important role in establishing the international trading of foodstuffs. This is now more than a 300 billion dollar business worldwide.

Probably the first food preservation patent was granted in 1691 to two Englishmen (Thomas Porter and John White).[20] As far as is known this patent, which was based on the use of heat, was never widely applied. The honor of successfully developing the first commercial process to sterilize food using heat belongs to Appert.[5] In 1810 he was awarded a patent and the prize offered by the French government for the successful development of a process that provided Napoleon's armies with ready-prepared food that could be stored for long periods of time at ambient temperatures. This invention formed the basis of the modern canned food business, which developed during the second part of the 19th century. Canned foods were thus among the first widely available convenience foods. Further milestones in the development of preserved foods are listed in Exhibit 1-1; methods of preservation are considered in detail in Chapters 2–15.

Despite considerable advances made in the preservation of foodstuffs, it has been estimated that between 10% and 50% of raw agricultural products (especially grains and vegetables) are still lost annually as a result of spoilage.[44,68] Some of the major quality

Table 1-1 Major Reactions Leading to Quality Deterioration of Foods

Reaction	*Example*	*Consequences*
Physical Change	Movement of water	Drying—toughening of texture
		Hydration—softening of texture; sogginess
		"Lumping" and aggregation of particulate foods
Chemical Change	Oxidation	Oxidative rancidity
		Color change
	Maillard reactions	Brown discoloration
		Texture change
Enzymic Activity	Polyphenol oxidase	Enzymic browning
	Lipoxygenase	Rancidity
	Lipase	Lipolytic rancidity
	Protease	Texture change
		Gelation
		Flavor change
	Amylase	Texture change
Microbial Activity	Growth of spoilage organisms	Food spoilage[*]
	Growth of toxigenic organisms	Foodborne intoxication[†]
	Growth of infective organisms	Foodborne infection[‡]
	Growth of functional organisms	Flavor change[§]
		Texture change
		Preservation

[*] **Minor products,** eg, thiols, esters, amines, and peroxides causing off-odors, flavor defects, discoloration, etc.
Major products, eg, lactic acid, acetic acid, H_2 and CO_2, causing souring, blowing, etc.
Enzymes, eg, proteases, lipases, and amylases causing textural and flavor changes, etc.

[†] **Growth and formation of toxic metabolites in food,** eg, neurotoxins by *Clostridium botulinum*, enterotoxins by *Staphylococcus aureus*.

[‡] **Presence or multiplication of infective microorganisms in food,** eg, *E. coli* 0157:H7 or *Listeria monocytogenes*.

[§] **Addition of lactic acid bacteria,** eg, to make fermented milk, vegetable and meat products; addition of **yeasts,** eg, to make breads, beers, and wines.

Exhibit 1-1 Milestones—Technologies for the Production of Safe and Stable Food

1810	Appert's canning patent published (France)
1864	Pasteur—"Pasteurization" of wine (France)
1870	Pasteurization of milk introduced (Denmark)
1874	Use of pressurized retorts for commercial canning (US)
1880s	Transportation of frozen meat from Australia to England
1890	Pasteurization of milk introduced (US)
1905	Chlorination of drinking water (UK)
1908	Sodium benzoate approved as a food preservative (US)
1920–22	Thermal process for canned foods based on the "botulinum cook" (US)
1924	"Holder" process introduced for pasteurizing milk, based on the destruction of *Mycobacterium tuberculosis* (US)
1928	Controlled atmosphere storage of apples to extend shelf life (Europe)
1929	Food irradiation patent published
1929	Marketing of quick-frozen foods (US)
1938	Controlled atmosphere storage of meat introduced (UK)
1947	Ice cream pasteurization regulations (UK)
1955	Sorbic acid approved as a food preservative (US)
1957	Concept of use of water activity as food preservation parameter published (Australia)
1963	Liquid egg (pasteurization) regulations (UK)
1977	WHO/FAO approve use of food irradiation up to 10 kGy
1988	Commercial use of ohmic sterilization of food (UK)
1991	Commercial use of high pressure for food pasteurization (Japan)
1997	WHO/FAO approve use of food irradiation up to 75 kGy

losses and spoilage changes occurring in foods are physical, for example, caused by the movement of water within food structures; some are chemical, for example, oxidation; and some enzymatic, for example, lipases. However, by far the majority of losses results from the activities of microorganisms (Table 1-1). Quality losses occur throughout the food chain, their rate and type depending on the food, storage conditions, and formulation.[29]

1.1.2 Foodborne Illness

As noted above, the association between the consumption of food and illness was recognized by early civilizations. Thus, Hippocrates (c. 460 B.C.) concluded that there was a connection between human disease and food consumption,[36] and one of the earliest references to the dangers of consuming the flesh of animals that had died from natural causes is contained in the biblical command: "and ye shall be holy men unto me: neither shall ye eat any flesh torn of the beasts in the field; ye shall cast it to the dogs" (Exodus 22:31).[12] Also, the relationship between the consumption of bread made with rye grain contaminated with the sclerotia of the fungus *Claviceps purpurea* (ergots) and disease was recognized during the 10th century. However, it was not until the late 19th century that proof was obtained that foodborne illness was caused by infectious and toxigenic microorganisms and that some of the specific causative microorganisms were first recognized.

The number of different microorganisms recognized to cause foodborne illness has increased from around 5 identified by the beginning of the 20th century, to 20 by the early 1950s to more than 40 by the early 1990s.[9] New foodborne agents continue to be identified and in the last 5 years at least six new ones have been reported. Most such agents are likely to have caused illness in humans for many years but were not recognized because of the absence of suitable detection methods or because some change in practice resulted in their increased presence in the human food supply chain.

Some of the years in which evidence of the association of a microorganism with foodborne illness was first reported are listed in Exhibit 1-2.

Since the 1950s, and somewhat parallel with the development of intensive farming practices,[9] a large increase has occurred in the number of reported cases and outbreaks of illness caused by well-established foodborne pathogens, such as salmonellas and campylobacters. The increasing number of reports of foodborne illness comes mainly from Western countries and from those few other countries that collect such statistics. While some of this increase is the result of improved reporting of cases and better methods of detection, the majority reflects a real increase in the incidence of illness (see Chapter 37). Although in most Third World countries data are not collected on such a basis that an assessment of the amount of illness or the causes can be made, foodborne illness is probably second only to malnutrition as the cause of death among children in these countries; it is sec-

ond only to respiratory disease as the cause of illness in Western countries.[9]

Some estimates of foodborne illness cases occurring worldwide are of extreme concern. These include an estimate made in the early 1980s that in Africa, Asia (excluding China), and Latin America up to 5 million deaths and 1 billion cases of gastroenteritis occur every year among children under the age of five.[43] While it is impossible to be certain how much of this illness and death results from the direct consumption of food contaminated with pathogenic microorganisms, it seems likely that such food is the main source. A more recent estimate of deaths among infants and young children in Third World countries suggests that 13 million die every year as a result of the combined effects of diarrheal diseases and malnutrition.[56] Estimates of food-associated illness in Western countries are also of considerable concern, with estimates that up to one in three people in these countries suffer from acute gastroenteritis annually[8,58]; 1%–5% of cases of illness lead to serious and chronic sequelae including rheumatoid conditions, atherosclerosis, and nutritional and malabsorption problems.[7,51] The World Health Organization (WHO) estimates that the annual incidence of foodborne illness worldwide is in excess of 1 billion cases and is increasing. The socioeconomic cost of such illness is extremely high as discussed in detail in Chapter 56.

Reasons for the increasing incidence of reported foodborne illness cases, in addition to those resulting from improved reporting and detection methods, have been variously attributed to a combination of the following factors[32,66,69]:

- ***Changes in agricultural practices,*** such as intensive farming, where breeding and husbandry practices have led to the rapid spread of human and animal pathogens throughout the herds and flocks in many countries. The current examples of such spread are *Salmonella enteritidis* PT4 in poultry and *S. typhimurium* DT 104 in cattle.
- ***Vertical integration of animal production processes and associated practices,*** eg, recycling waste products from slaughter houses back into the animal food chain, via animal feed, resulting in the build-up of agents such as salmonellas in poultry flocks (Chapter 20) and bovine spongiform encephalopathy (BSE)-causing prions in cattle herds (Chapter 57).
- ***Lifestyle changes,*** such as more travel by persons to countries where standards of hygiene are lower than those in their home countries, leading to exposure to microorganisms to which they have no immunity.[60] Increased consumption of foods (particularly snack foods) outside the home may also lead to exposure to foodborne pathogens. Such foods are often prepared under unhygienic and unsuitable conditions by ill-trained staff, leading to the sale of unsafe foods.
- ***Demographic changes,*** leading to the increased susceptibility to infection of numerically larger sections of the population such as the very young, the elderly, persons under medical care, and the immunocompromised; it has been estimated that 20% to 25% of persons in Western communities belong to this category.[55,62]
- ***Malnutrition*** among Third World populations, leading to increased susceptibility to disease.[55,56] This situation is made worse by civil unrest in many parts of the world, resulting in large numbers of people forced to leave their homes, and then exposed to extreme conditions, leading to the rapid spread of foodborne and waterborne illnesses such as cholera and dysentery.
- ***Globalization of the world's food supply,*** leading to longer supply chains (more persons and food handling procedures involving potentially increasing risks). Increased world trade in foods and food raw materials is an emerging concern.[45,53,63] Such foods increasingly comprise fresh produce and other perishable foods transported by air, in contrast to the preserved foods and raw materials for further processing traditionally imported by sea. Examples of fresh pro-

duce that have recently caused illness are lettuce exported from Spain causing bacillary dysentery in Norway, Sweden, and the United Kingdom (UK),[46] and raspberries exported from Guatemala causing cyclosporiasis in the United States (US) and Canada.[34]

Other factors claimed to possibly or potentially increase the incidence of foodborne illness include the following: global warming[13]; less use of additives, such as nitrite, to preserve foods; and the increased marketing of mildly preserved, less processed foods, such as modified atmosphere packed chill-stored cooked meats and mildly heated in-pack heated foods prepared by the "Sous vide cuisine" process.

Because the types of foods involved in foodborne illness very closely reflect the types and sources of foods consumed by a population, their microbial ecology, and the methods of preparation for consumption, there are significant differences from country to country.[9] While there is much published information on the types of foods involved worldwide, most of these data have not been collected and collated in a form that can be used to estimate the prevalence of foodborne illness or the types of microorganisms involved. In most Western countries, unprocessed poultry and red meats are mainly reported to be involved in foodborne illness, with less than 5% of reported incidents caused by manufactured foods.[15,62] However, where the latter foods are involved in an incident, the number of cases of illness can be very high. For example, in 1994 there was an incident in the US involving *Salmonella enteritidis* contamination of a pasteurized ice cream mix that resulted in an estimated 224,000 persons becoming ill.[33] Examples of estimated financial costs of food poisoning incidents resulting from commercially produced foods in the UK are given in Exhibit 1-3. Further examples of costs and incidents are presented in Chapter 56.

1.2 SOURCES OF FOODBORNE PATHOGENIC MICROORGANISMS

The recognition of the sources of foodborne pathogenic microorganisms and the understanding of the factors that may lead to them causing illness are important when considering the means for their control. For the most part, such organisms are zoonotic, ie, of animal origin, and include such organisms as *Escherichia coli* O157:H7 and *Campylobacter jejuni*, or are widespread in the environment (geonotic) such as *Listeria monocytogenes* and *Bacillus cereus*. The illnesses they cause generally result from the contamination of raw agricultural produce, often combined with poor hygienic practices during preparation for consumption. Such practices include the following: undercooking, cross-contamination onto other foods, recontamination of the cooked product, and storage of preprepared foods at temperatures and for time periods that allow microbial growth to occur.[15,60]

Some foodborne pathogens, such as *Salmonella typhi* and the hepatitis A virus, are specifically of human origin and contaminate foodstuffs during primary production via sewage, for example, or during preparation for consumption as a result of poor personal hygiene by a food handler who is a carrier. Human carriers are also of concern in the contamination of foods with *Staphylococcus aureus*, *Shigella* spp. and Norwalk and Norwalk-like viruses (Chapters 46, 47, and 52).

Exhibit 1-3 Examples of Costs of Foodborne Illness in the UK Caused by Commercially Produced Foods

Year	*Illness*	*Food Involved*	*Cost Estimate**
1964	Typhoid	Canned corned beef†	£30 million
1978	Botulism	Canned salmon†	£4.0 million
1979	Staphylococcal food poisoning	Canned corned beef†	£2.0 million
1987	Salmonellosis	Infant dried milk	£3.0 million
1989	Salmonellosis	Salami sticks†	£5.0 million
1989	Botulism	Hazelnut yogurt	£6.5 million

*Approximate costs (inflated to 1997 costs) based on available information on costs of investigations, losses of earnings of victims, medical costs, and industry costs (recall, destruction of stock, loss of business).

†Imported product.

Tables 1-2, 1-3, and 1-4 list foodborne pathogens found on slaughtered animals, fish, and vegetable crops, respectively, and some of the basic hygiene measures used for their control.

1.3 CONTROL OF FOODBORNE PATHOGENIC MICROORGANISMS

Prevention of foodborne infections and disease is a multifactored process requiring establishment of control throughout the whole food supply chain. The first line of defense against contamination by microbial pathogens is to prevent the pathogens from contaminating food animals and crops at the primary production stage. The second line of defense is to avoid further contamination and growth during harvesting and post-harvest handling, and where possible, to introduce one or more steps, during their processing or their use in a manufactured food that will inhibit or kill the contaminating microorganisms or destroy any preformed microbial toxins.

The first line of defense, while potentially the most effective, can be problematic because of the large number of possible sources of microbial contamination of food crops and animals prior to their harvest. This is best illustrated by the Salmonella Transmission Cycle shown in Figure 1-1, which shows the many potential sources of salmonella contamination of food animals.[10]

Treatments to make farm animals more resistant to infection by foodborne pathogens by blocking their attachment to the animal's intestinal tract are under evaluation by various research groups. Methods being studied include the use of competitive exclusion,[59] the development of vaccines,[54] and the long-term possibility of introducing resistance genes into an animal's gene pool.[9]

Where control of microbiological contamination cannot be achieved at the primary production stage, some control can be obtained during a manufacturing or processing step, or by the preparer or consumer in the case of a raw food cooked prior to con-

sumption. However, control achieved at later stages is seldom as effective as control at the primary production stage because contamination becomes more widely spread and more difficult to control. This leads to the potential contamination of food handling areas, of additional products, and of food handlers. An exception to this general rule is the pasteurization of milk, which is demonstrably a very effective procedure for destroying infective pathogens. When pasteurization is combined with hygienic handling pre- and post-pasteurization, excellent control of the microbiological hazards associated with milk and milk-based products results (Chapter 22). This introductory chapter will only consider the basic strategies for control. However, further procedures for controlling microorganisms in processed and manufactured foods are found in Chapters 2–16. Control requirements for the main food commodities are discussed in Chapters 17–36.

1.3.1 Strategies for Control

Whether a microbiologically contaminated food can be safely consumed depends on the numbers and types of pathogenic microorganisms or the amount(s) of microbial toxins present at the point of consumption and the susceptibility to infection or intoxication of the person consuming that food. The purpose of all control procedures is to ensure that potentially hazardous levels of microorganisms or toxins are not present in a food at the point of consumption. Similar control strategies apply to pre-

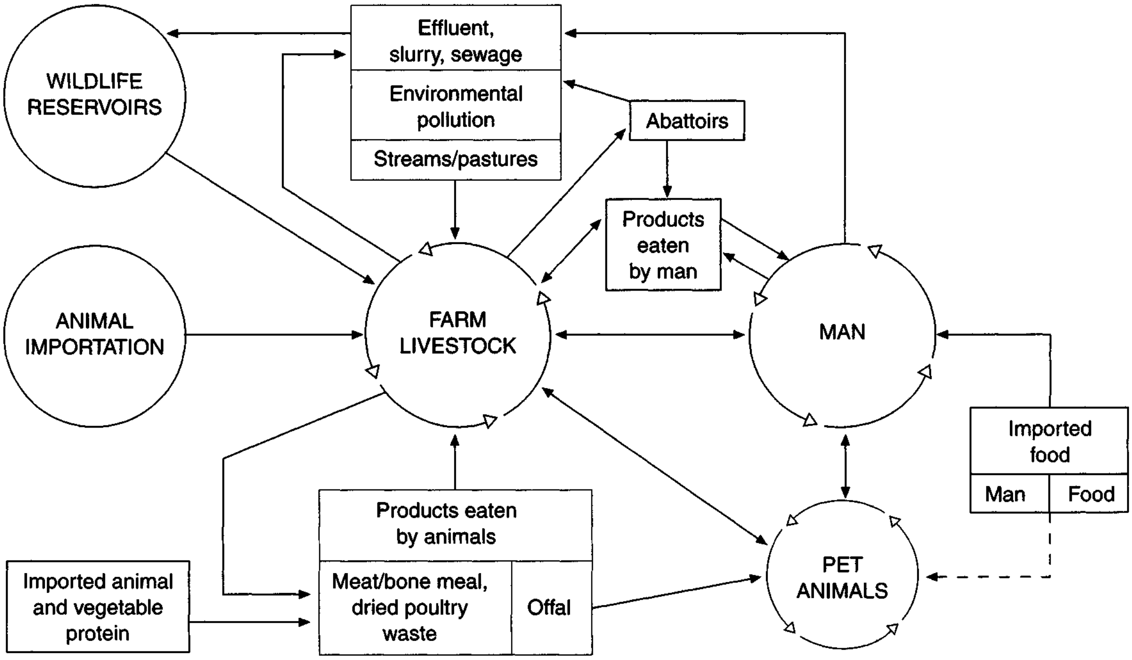

Figure 1-1 Cycle of Salmonella Transmission. *Source:* Reprinted with permission from A.C. Baird-Parker, Foodborne Salmonellosis, *The Lancet,* Vol. 336, pp. 1231–1234, © 1990, The Lancet Ltd.

venting or slowing the growth of spoilage microorganisms and thus preventing their metabolic products from causing spoilage.

Strategies for control of microbiological hazards in foodstuffs have evolved over many years, and this process of evolution continues with development of structured and quantitative risk assessment and hazard analysis techniques. These techniques are fully described and discussed in Chapters 58 and 65 and are summarized in Section 1.4 of this chapter.

The traditional approach to food control used by both food producers and the regulatory authorities has been mainly to inspect a production unit for compliance with General Hygienic Practice (GHP) requirements (often defined in law) and where appropriate to take samples of product to the laboratory for microbiological and other forms of testing.[39] Good Hygienic Practice requirements include basic requirements for the following: hygienic design, construction, operation, and sanitation of food production premises and equipment; the hygiene of operations used in the preparation, processing, storage, and use of raw materials and products; and the education and training of operatives in good personal hygiene and good hygienic practices[2,27] (Chapters 58 and 59). Good Hygienic Practice requirements are usually included in Good Manufacturing Practice (GMP) documents.

Traditionally, food producers have employed quality assurance or control personnel to check that GMP requirements are met and to take samples for microbiological and other forms of testing. The regulatory authorities have employed inspectors to monitor food producers and distributors, with the basic aim of enforcing food hygiene legislation and other regulations relating to the production and sale of foodstuffs. The usefulness of these procedures has been subject to considerable scrutiny in recent years. One of the main reasons for this is that despite the large amount of new hygiene legislation enacted in many countries in recent years, the number of cases of foodborne illness has continued to rise. Also, the increasing complexity and speed of modern food processing equipment (much of which is enclosed and cannot easily be inspected) makes traditional inspection procedures even less effective. Microbiological testing, the other linchpin of traditional control, has increasingly been demonstrated to provide poor assurance that production is under control. As the outcome of any testing is generally only known long after production has been completed and the product packed, the result can have no direct influence on the controls applied during production. Also for statistical reasons, the confidence of decisions as to product acceptability based on microbiological testing will always be poor (Chapter 60).

The costs involved in setting up and running modern food production plants and facilities are very high. Hygiene measures to ensure that foods produced are safe and wholesome are a significant element of these costs. Much of the existing food hygiene legislation is essentially GHP requirements and contains general phrases such as "all articles, fittings, and equipment with which food comes into contact shall be kept clean"; "where necessary, disinfected, sufficient for the purposes intended"; "where necessary appropriate facilities must be available" (European Economic Community [EEC] 93/43 Annex I). Such imprecise phrases, while necessary in legislation designed to meet the basic GHP/GMP requirements of large sectors of the food industry, require interpretation by inspectors checking for compliance and by plant owners wishing to set up food production facilities that comply with legislation. Their impreciseness has the potential to lead to much misunderstanding and wasted effort by inspectors and food plant owners and often result in the nonoptimal implementation of hygiene measures and poor cost benefit.

Government bodies such as the Codex Alimentarius Commission[17] have recognized that for many foods more precise advice on the hygienic design and control of food production plants is needed by both food producers and regulatory authorities. The Commission, therefore, recommends that in addition to meeting basic GHP requirements, specific Codes of Hygienic Practice should be developed by the Codex Alimentarius Food Hygiene Committee for the production of microbiologically sensitive foodstuffs, and that the principles of hazard analysis critical control point (HACCP) be applied throughout the food supply chain and to all foodstuffs.[27] Similar recommendations are contained in the European Union General Food Hygiene Directive[2] and are incorporated in the laws of many countries.

The proactive approach of HACCP, based on the application of structured hazard analysis and the identification of specific means of control of the identified microbiological hazards associated with the production of a specific foodstuff, contrasts sharply with the generally applied traditional approach to control described above. The application of HACCP is based on seven "principles."[27] These principles are as follows:

1. Conduct a hazard analysis to identify the microbiological and other product safety hazards of concern in a particular food operation.

2. Determine the Critical Control Points (CCPs) (places, procedures, etc.) where an identified hazard can be controlled.
3. Establish critical limits for control at the CCPs (that separate acceptable from unacceptable control).
4. Establish a system to monitor control of the CCP (to respond to a control deviation before a critical limit is exceeded).
5. Establish the corrective action to be taken when monitoring indicates that a particular CCP is not under control.
6. Establish procedures for verification to confirm that the HACCP system is working effectively.
7. Establish documentation concerning all procedures and records appropriate to these principles and their application.

The application of these principles is fully described and illustrated in Chapter 58.

The wide adoption of the principles of HACCP by regulatory authorities and industry as an essential part of food control is based on recognition by all involved in the food chain of the power of this procedure and the advantages gained by its application. By traditional inspection, an authority will get little more than a snapshot of the effectiveness of the hygiene control procedures in place in a food plant at the time of inspection. In contrast, where a HACCP plan has been properly developed, implemented, verified, and documented, the authorities can inspect the plan to obtain an accurate picture of the control measures in place.[57] They also are able to understand the basis for these control measures and are able to review the records obtained of monitoring control at the Critical Control Points to ensure control within the defined Critical Limits. Inspectors can also see what actions were taken when these limits were exceeded. The advantages to industry applying HACCP are as follows:

- focusing technical resources into those operations and procedures that are critical to ensuring product safety
- providing a framework for managing safety
- providing better security of product safety and reduced risks of product failure and financial losses
- enabling product safety features to be designed into a product and its associated process at its design stage.

It is generally agreed that HACCP is the most cost-effective means of ensuring food safety and reducing product losses due to spoilage (Chapter 58).

The application of HACCP has resulted in less use of microbiological criteria as a primary means of control. However, microbiological criteria will continue to be used by regulatory authorities for border control (particularly in the absence of other information indicating that proper control has been applied during production and distribution of an imported foodstuff), and may also be used to audit production within a country. In addition, microbiological criteria will continue to be used by industry in purchasing agreements and for some internal control purposes. It is important that if microbiological criteria continue to be used as a means of food control that they should be properly formulated and their limitations fully understood by their proposers and users. The requirements for establishing and using microbiological criteria are fully described in Chapter 65.

1.4 ASSESSMENT OF MICROBIOLOGICAL RISKS

It is increasingly accepted by regulatory authorities and by industry that microbiological control requirements for foodstuffs should be firmly based on an understanding of the microbiological risks that need to be controlled. Risk assessment has been described as the science of understanding hazards, the likelihood that they will occur, and the consequences of their occurrence.[1] The assessment of microbiological risks associated with foodstuffs has been the concern of microbiologists throughout most of the 20th century. In the 1920s, such assessments were used in the United States to establish safe heat processes for canned foods, based on the destruction of *Clostridium botulinum* spores,[24] and for pasteurized milk based on the destruction of cells of *Mycobacterium tuberculosis,* and later, *Coxiella burnetii.*[48] More recently, safe heat processes have been established for *Escherichia coli* O157:H7 and *Listeria monocytogenes* (Chapters 43 and 44). Microbiological criteria, based on a form of risk assessment, were introduced by the International Commission on the Microbiological Specifications for Foods (ICMSF) in the early 1970s and are used for establishing microbiological criteria by regulatory authorities and by the food industry throughout the world.[27,40]

The recently implemented World Trade Organization (WTO) Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement)[3] requires that countries signatory to the agreement base their laws concerned with protecting human, animal, and plant health on a process of risk assessment, with the aim of ensuring that health protection measures are scientifically based and are not used as disguised restrictions to trade. Thus, the SPS Agreement requires food safety legislation to be scientifically based and requires risk assessment to be applied, for example, when introducing microbiological requirements for controlling imported foods. This requirement has fueled renewed interest in developing methods for assessing microbiological risks on a quantitative basis.[16,49] The approaches to, and the difficulties in, applying quantitative risk assessment procedures to quantify microbiological risk are described and discussed in detail in Chapter 65. However, one of the main problems is the general absence of sound data on the relationship between a particular concentration of pathogenic microorganism and the probability of this concentration of microorganisms causing illness if it is consumed in a food, ie, dose-response data. In addition to the inherent virulence of individual strains, there are many factors affecting the infectivity and the illness-causing potential of a foodborne pathogen.[19] These are listed in Table 65-2 of Chapter 65 and illustrate the large range of different and interacting factors that can affect infectivity and disease.

To collect reliable quantitative information on the effect of these factors on infectivity and the subsequent initiation of illness by a particular microbial pathogen is a daunting task. When considering a microbiological risk assessment for a particular food, the following knowledge should be required:

1. Types and numbers of foodborne pathogenic microorganisms, including toxic products of their metabolism, that may be present in a food raw material or ingredient, or that may be introduced during its transformation into a food product.
2. Effect of any processing (such as heating, curing, drying, acidulation, or addition of preservatives), or packaging eg, modified atmosphere packaging, on the survival or destruction of any pathogenic microorganisms or toxins as introduced in item #1 above.
3. Effect of conditions during storage and distribution such as freezing or chilling of the foodstuff and the effect of any procedures used for its preparation for consumption on the increase, decrease, or survival of any pathogenic microorganisms as introduced in item #1 or surviving (item #2).
4. Likely susceptibility of individuals in the consumer group for which the product is targeted, eg, infant, child, or hospital patient, to infection or intoxication by the microorganisms or toxins present in the foodstuff at the time of consumption.

To collect, collate, and assess the microbiological and medical knowledge for identification of the maximum concentration of an agent that is acceptable in a foodstuff requires input from several expert groups. Such groups could be industry- or government-led depending on the aim and scope of the particular type of assessment undertaken. For instance, a body responsible for assessing the microbiological risks associated with a particular pathogen or toxin in a foodstuff would be concerned with the collection of epidemiological, medical, microbiological, and toxicological information concerning the probability and extent of illness arising from the presence of an amount of the agent in foods consumed by a particular population. Such a risk assessment body would be independent, involving mainly academia and public health experts, with some input from industry on such matters as food consumption patterns and procedures generally applied to the processing or preparation of target foods for consumption. After establishing that a risk exists that needs managing, a risk management group would be set up to identify options for reducing any unacceptable risks to acceptable levels. This independent group would have greater government, consumer, and industry input so that policy and consumer issues can be considered and technically achievable options for control can be identified. Thus, the risk management group would be responsible for taking the output from the risk assessment body that has made a scientifically based estimate of the likelihood of a particular microbiological hazard causing harm, and converting this output, ie, the risk estimate, into a series of quantified control measures, eg, food safety objectives, that can be then be communicated to industry (part of the process of risk communication).

The processes of risk assessment, risk management, and risk communication are known collectively as risk analysis and the principles for performing these processes for microbiological and other biological risk assessments for foodstuffs have been subject to much recent international debate.[4,18,25,26] The relationship between governmental activities involved in risk analysis and the use of the output of such a risk analysis by a food producer to develop an internal control system is shown in Figure 1-2.

Microbiological risk assessment procedures are still in their infancy and are not sufficiently well developed to provide reliable and quantitative esti-

mates of microbiological risk (Chapter 65). However, much progress has been made in applying microbial modeling and computer simulation techniques to quantify the microbiological hazards associated with certain processes used in the food industry. These techniques clearly are of value in establishing critical limits (control parameters for CCPs) on a more scientific basis, and for evaluating the performance and equivalence of HACCP plans.[16,22,52,65]

1.5 THE ROLE OF LEGISLATION

Food laws protect the consumer against fraud, adulteration, and contamination of food; they also protect the honest manufacturer and trader against unfair competition. Many Roman and Greek civil laws were aimed at protecting their peoples against such malpractices. Further, many food laws and statutes introduced in the Middle Ages and the Renaissance were particularly aimed at protecting the public from the use of false weights and measures and the sale of adulterated food.[36]

Modern food law dates back to the 19th century, and not surprisingly the first of such UK laws was the Adulteration of Food Act of 1860, which remains the foundation of UK food law.[64] Legislation concerning the hygiene of foodstuffs was developed somewhat later, with the first regulations being introduced at the turn of the 20th century. The regulations mainly concerned meat inspection in recognition of the large amount of illness resulting from the consumption of contaminated meat.

Hygiene legislation evolved throughout the 20th century and has included the regulation of important specific processing measures, such as the time and temperature requirements for the pasteurization of milk[48] as well as the introduction of general hygiene measures via general hygiene regulations within Food and Drug Acts and specific requirements in statutory codes.[37] Increasingly, it has been recognized that much of the existing national food legislation conflicts with requirements in other countries and thus leads potentially to nontariff barriers to trade. Further, many requirements in existing national and international hygiene legislation are based on perceptions of hygiene needs and value judgments of general control requirements rather than on a scientifically based assessment of need, based on an assessment of risk and identification of specific and quantifiable measures for the control of any unacceptable risk. Thus, there is much activity in reviewing existing legislation and implementing new legislation based more heavily on the scientific process of risk assessment and the identification of specific food safety objectives.[26] This change is reflected in the UK Food Safety Act 1990[64] and the ongoing review of the European Union hygiene regulations concerning animals and animal products. Changes are taking place throughout the world following the WTO/GATT Sanitary and Phytosanitary (SPS) Measures Agreement.[3] This follows the need, specified in the SPS Agreement, for member governments to promote the concepts of equivalency, transparency, and harmonization and the need to develop food control legislation using risk assessment techniques developed by international organizations such as the Codex Alimentarius Commission.[17]

Hygiene requirements in food legislation should be proportionate to real health risks and based on the best available knowledge of the public health risks associated with particular foodstuffs. Legislation should also be sufficiently flexible to accommodate changes in scientific knowledge, such as the identification of new foodborne pathogens, and advances in food technology, such as the development of new processing methods and food preservation techniques. Hence, legislation should contain only the objectives and principles for obtaining a safe food and should require industry to be responsible for demonstrably implementing appropriate control procedures that will ensure that these objectives and principles are fully met.[38]

Enforcement of hygiene legislation is an essential part of the activities of a food control agency. Much of current enforcement is probably ineffective for reasons described earlier in this chapter. The empowerment and proper training of enforcement officials in risk and hazard assessment procedures, along with basic knowledge and understanding of food microbiology and modern food processing technologies, are essential if such officials are to provide an effective control and advice function.

1.6 THE FUTURE

1.6.1 The Food Supply

According to United Nations statistics, the world's population increased from 2.5 billion in 1950 to 5.7 million in 1995 and will increase to 8.3 billion by 2025. Over approximately the same time period, the urban population increased from 17% of the population in 1950 to 35% in 1990 with an estimate to increase to 54% by the year 2020.[41] Much of the population growth and increased urbanization will take place in Third World countries. The absence of clean water and basic public health control measures, together with the poor housing and malnutrition associated with poverty in urban areas, will potentially lead to more foodborne and waterborne disease.[31] It has been estimated that the global food supply will have to increase by 75% over the next 30 years in order to feed the expected world population growth.[21]

The challenge to governments and food producers is to meet this food demand, recognizing that the majority of the demand will be for access to a safe and nutritious supply of food by Third World nations. This will only be achieved by the close collaboration of molecular biologists, economists, agronomists, food scientists, and food microbiologists. The molecular biologist's role will be to explore ways to improve the productivity of food crops, including the resistance to microbial infection and diseases. The role of the food microbiologist, in addition to improving food safety, will be to identify better ways to reduce spoilage losses in basic food commodities, particularly those arising during storage and transportation to the expanding urban areas within Third World countries. Current world food shortages could be reduced if current losses through microbial spoilage were significantly reduced, and if more cost-effective means were available to preserve and transport food where it is in excess to where need exceeds availability.

An adequate supply of safe drinking water is not available in many Third World countries. Such water will increasingly be required for agricultural and food processing in these countries and will put further pressure on water supplies. Similar concerns of water availability are present in Western countries, with the effects of global warming increasing these concerns. The development of internationally accepted procedures for disinfecting water for reuse in food processing is under consideration by the Codex Alimentarius Commission. There is a particular need to develop means of detecting reconditioning system failures because such failures can lead to catastrophic public health problems.

The demand among consumers in developed countries for "in-season" fruits and vegetables throughout the year has led to a large trade in fresh produce from Third World countries. This trade provides essential revenue for these countries and is expected to increase, as will further processing of such fruits and vegetables in the country of origin. However, as noted previously, such produce may be contaminated with a wide range of foodborne pathogens (Chapters 25 and 27), and effective means for preventing and eliminating such contamination are needed.[14] The transfer of food technology knowledge and microbiological expertise to Third World countries is needed for the production of microbiologically safe foods for home consumption and for distribution throughout the world.

The growth in the convenience foods market, particularly seen in the developed countries over the past 20 or so years, and reflecting the changing lifestyles of the peoples of these countries, is also being developed in an appropriate form in Third World countries. Examples of "hurdle technology" to preserve some of the traditional foods of these countries are discussed and described in Chapter 14. In Western countries, the demand is for such foods to appear to be less processed and to have a "fresh" and more natural appearance and taste. Thus, the trend is to use less preservatives in foods and to generally apply processes that cause less damage to the organoleptic characteristics of the food. Therefore, increased growth in the chilled and frozen food sectors is expected to continue. However, the energy demand for the storage of such foods is particularly high. As energy costs and the associated environmental concerns increase, the need for development and application of preservation technologies that enable good storability at ambient temperatures and give equal consumer satisfaction will increase. Such products are particularly relevant to meet the needs of Third World countries.

1.6.2 New Technologies

To meet the consumer demands described above, the food industry has explored, and continues to explore, the application of new technologies to preserve foodstuffs. Thus, there has been much research into processes that use less or no heat to commercially sterilize foods. Such developments include the use of electrical resistance (Ohmic) heating, high pressure, pulsed electric fields, and possibly even pulsed light and pulsed high intensity magnetic fields; these techniques are discussed further in Chapters 2 and 13.[28] Other research has centred on exploring the potential incorporation into foods of natural antimicrobial agents from plants and animal tissues and of such agents produced by microorganisms (Chapters 2, 12, and 13).

While the effectiveness of many of these developments has been demonstrated under experimental conditions in the laboratory, few have progressed to commercial application because of scientific limitations or because the available technology for their application had limitations. A potential further difficulty with many of these applications is the ability to demonstrate the degree of microbial lethality achieved. For instance, should high pressure sterilization become technically possible, what should be the basis for demonstrating to a regulatory authority that the process will ensure the same degree of microbiological safety as the current thermal process? There are several problems in demonstrating equivalency with two such processes. The first is the different microbial inactivation kinetics of the two processes and, second, their different effectiveness against specific pathogenic microorganisms.[28] It is arguable that traditional approaches to microbiological safety assurance are inadequate for the judgment of safety of new process with different inactivation kinetics, and that new rationales should be developed based on modern risk assessment procedures.

There is increasing awareness that there are interactions between microorganisms and foodstuffs resulting in microorganisms adapting to their environment, and that virulence and survival of pathogens can be directly affected by a particular preservation system.[6,47] Such interactions, their effects on gene expression, and their significance to the use of existing and new preservation technologies needs to be studied, ie, do they change our assessment of the degree of microbiological safety assurance provided by these technologies?[11]

Parallel with research into new preservation technologies have been developments in the design and the construction materials used for food processing equipment, allowing a plant to operate hygienically for long time periods and thus improving production costs. These development are considered in Chapter 59.

Other new technologies recently applied to improve the microbiological safety of foods include the incorporation of antimicrobial agents into food contact materials and the incorporation of sensors into packaging material that provide visual evidence of time and/or temperature abuse.

1.6.3 Foodborne Illness

The prevalence of foodborne pathogens and epidemiological knowledge of the extent, sources, and causative factors that lead to foodborne illness remain unknown in many parts of the world. Even in Western countries new agents transmissible through foods and capable of causing illness continue to be found. Many of these do not cause classic acute gastroenteritis but long-term chronic illness often of a serious debilitating nature. One of the most recent of these has been the demonstration that "new variant" Creutzfeldt-Jakob Disease (v-CJD) in humans is almost certainly caused by the consumption of beef contaminated with the prions that cause bovine spongiform encephalopathy (Chapter 57).

What other agents will become a concern as a result of changes in food consumption, production, and processing practices, or discovered as a result of the development of new detection methods (Chapters 61–64)? This cannot be predicted but there are a number of trends that will potentially increase the risk of foodborne illness. These include an increase in the numbers of persons in populations more susceptible to illness because of some deficiency in immune competence as a result of age, disease, or medical treatment (Chapter 55). In addition, there is the likely increase in susceptibility to foodborne illness of persons living in Western countries as a result of less contact with foodborne pathogens and, hence, less triggering of the immune system (illness may more frequently arise as a result of increased travel to Third World countries and/or increased importation of foods from Third World countries). Balancing these concerns is the recognition of these risks and the wider use of labeling and targeting food consumption advice at the "at-risk" consumer groups and travelers, together with the wider influence of bodies such as the FAO and WHO sponsoring training courses on HACCP and food control procedures throughout the world.

There is a need for increased surveillance of foods in all countries to determine the prevalence of foodborne pathogens and to identify potential new public health concerns that may require the introduction of new legislation or some other form of control. One particular concern that requires concerted international action arises from the increasing recognition of antibiotic-resistant organisms in the food chain and the potential for these organisms to transfer such resistance to clinically important microorganisms.[23,30,50] Such information, together with all epidemiological information on foodborne illness, should be collected and collated on a world basis[67] and disseminated via the Internet.

1.7 CONCLUDING REMARKS

It is of concern that despite the vast accumulation of knowledge of the microbiology of food spoilage and foodborne pathogenic microorganisms and our ability to document this knowledge in a book such as this, about one-third of the world's food produce is lost annually as a result of microbial spoilage, and a vast amount of microbially caused foodborne illness continues to occur throughout the world. There can be no doubt that there have been significant advances in our ability to produce microbiologically safe and stable foods, and that for the most part, foodborne illness and food spoilage are preventable. So why are we so unsuccessful? What appear to be lacking are sufficiently strong incentives to apply our existing knowledge to those activities and to those parts of the food chain where these would be most effective. Thus, if we want to significantly reduce foodborne illness, we must reduce the presence of the main causative agents, ie, *Salmonella* and *Campylobacter* species, in our food animals. If we want to prevent spoilage, we should store our foods under conditions that prevent their deterioration. Why do we not apply these preventive measures? The main reason is undoubtedly the cost benefit of applying the currently available methods. The challenge to food microbiologists in the 21st century is to identify control measures that are practical, widely applicable, and cost-effective. It is then up to governments to ensure that these measures are implemented and enforced.

2.1 INTRODUCTION

Most foods lose some degree of quality and shelf life following harvest, slaughter, or manufacture, depending on the type of food, its composition, formulation, processing, packaging, and conditions of storage. Loss of quality and shelf life may occur at any stage from the acquisition of raw materials to the eventual consumption of the finished product. These stages include storage, handling and assembly of ingredients, processing, packaging, distribution, retail display, transport, storage, and preparation for consumption. The stages, under varying degrees of control, are designed to provide a shelf life that ensures the safety and high quality of the finally consumed product.

The principal reactions that cause loss of food quality are well known. Consequently, they are the major targets for effective preservation, the prevention of quality loss in all its forms. Quality loss reactions are relatively few in number, and include physical, chemical, enzymic, and microbiological[50] (see Table 2-1).

When preservation fails and one of these reactions accelerates or escapes control, there may be a wide range of consequences. At the one extreme these may be trivial, though undesirable, changes in color, flavor, or texture of the food. At the other extreme, the most serious forms of quality loss are those associated with the presence or multiplication of certain microorganisms. These range from those that cause

Table 2-1 Major Reactions Leading to Quality Loss of Foods

Microbiological	*Enzymic*	*Chemical*	*Physical*
Growth or presence of toxinogenic microorganisms	Hydrolytic reactions catalyzed by lipases, proteases, etc	Oxidative rancidity	Mass transfer, movement of low molecular weight (MW) compounds
Growth or presence of infective microorganisms	Rancidity catalyzed by lipoxygenases	Oxidative and reductive discoloration	Loss of crisp textures
Growth of spoilage microorganisms	Enzymic browning	Nonenzymic browning	Loss of flavors
		Destruction of nutrients	Freeze-induced structural damage

various degrees of spoilage, which nevertheless may result in economically important losses of foods, to the most hazardous of the food poisoning microorganisms that cause life-threatening diseases (Table 2-2). While most preservation techniques aim to control all the forms of quality loss, the overriding priority is always to minimize the occurrence and the growth of microorganisms, particularly those that cause food poisoning.

Table 2-2 Major Consequences of Quality Loss of Foods

Nature of Quality Loss	*Consequence of Quality Loss*
Presence of toxins Presence of pathogenic microorganisms	Hazard to the consumer
Microbial spoilage	Loss of food Limitation of shelf life
Potential microbial hazard	Inability to distribute and market product Product recall
Unacceptable rate of oxidation Unacceptable change in texture Development of rancidity Color change Flavor loss Texture change Poor keepability due to changes in color, flavor, texture	Increased packaging and distribution costs Limitation of shelf life Poor quality of marketed food

The various forms of microbiological risk are controllable to a large degree by a range of preservation techniques, most of which act by preventing or slowing down microbial growth (eg, chilling, freezing, drying, curing, conserving, vacuum packing, modified atmosphere packing, acidifying, fermenting, or adding preservatives). A much smaller number of techniques act by killing microorganisms (eg, pasteurization and sterilization by heat and, to a much lesser extent, by ionizing radiation). Complementary techniques restrict the access of microorganisms to processed products (eg, clean handling, aseptic processing, and packaging).

A major trend is that new and "emerging" preservation techniques act primarily by inactivation (eg, ultrahigh pressure; high voltage electric pulse treatments; combined heat, ultrasonication, and pressure; the addition to foods of bacteriolytic enzymes).[10,27,40] A further trend is the development of higher quality products that are less "heavily" preserved, more natural, freer from additives, and nutritionally healthier. This trend results mainly from the food industry's reactions to the changing lifestyles of consumers (Exhibit 2-1).

Less severe preservation procedures are therefore being developed that make increasing use of (1) preservative factors in combinations (hurdle technology) in order to deliver less damage to product quality; (2) new methods of heating that are better controlled and therefore deliver milder heat to products; (3) combinations of precooking and refrigeration that produce foods with high quality and

Exhibit 2-1 Trends in Consumer Requirements and Food Industry Reactions

Trends in consumer requirements

- Improved convenience
  - —in preparation, storage, shelf life
- Higher quality
  - —in flavor, texture, appearance
- Fresher
- More natural
  - —with fewer additives
- Nutritionally healthier
- Minimally packaged
- Safer

Food industry reactions

- Milder processing
  - —minimal overheating
  - —less intensive heating
  - —nonthermal alternatives to heat
- Fewer additives
  - —less "chemical" preservatives
- Use of "hurdle" technologies or "combination preservation" systems
- Evaluation of natural antimicrobial systems as food preservatives
- Less use of salt, saturated fats, sugar; more low-calorie foods
- Reduced, environmentally friendly packaging
- Elimination of food poisoning microorganisms

extended shelf lives; (4) modified atmosphere packaging to retain quality longer; and (5) use of more natural antimicrobial systems.

Many of the existing and emerging preservation techniques were derived empirically following many years of observation and research. However, more recently, new physiological investigations and "mode of action" studies are revealing that many of the most-used techniques act by interfering with the homeostatic mechanisms that microorganisms have evolved in order to survive extreme environmental stresses.[92] An understanding of the bases of the stress reactions is encouraging the development of more soundly based preservation procedures, aimed at increased control of the microorganisms that may cause foodborne disease or bring about the spoilage of foods.[43]

2.2 MICROBIAL TARGETS FOR FOOD PRESERVATION

While the number of microorganism types that cause food poisoning is relatively small, many types can cause spoilage. The principal food poisoning microorganisms, dealt with in detail in the various chapters of this book, are listed in Table 2-3 to indicate their relative resistance to heat and their ability to multiply at low temperatures. The major food spoilage microorganisms are not dealt with as specific genera or species in this book but rather, are discussed in the chapters dealing with particular food products and commodities. See also other major texts.[12,26,35,52,74] In Table 2-4 the most important of the spoilage organisms are categorized in such a way as to highlight not only their taxonomic relatedness but also, more importantly with regard to spoilage, the physiological and biochemical characteristics that govern their interactions with, and effects on, foods.

2.2.1 Gram-negative, Catalase-Positive, Oxidase-Positive Rods

Gram-negative, catalase-positive, oxidase-positive rods include the aerobic bacteria that grow rapidly and tend to dominate the spoilage flora of fresh meat,[15] fish,[46] poultry, eggs, and other high pH/high water activity (a_w), protein-rich foods and vegetables.[56] These bacteria grow in the presence of oxygen, at chill and at ambient temperatures. They include many psychrotrophs, such as some *Pseudomonas* species, that are able to multiply below 0°C. They are able to grow in simple media and are characterized by their ability to metabolize a wide range of organic compounds. With few exceptions, they are not particularly tolerant of extreme environmental conditions so that, for example, slight reductions in water activity (eg, in cured meats) or reductions in pH (eg, in marinaded fish products) tend to prevent their growth and encourage more tolerant groups (see below). *Acetobacter* oxidizes ethanol to acetic acid in alcoholic beverages and souring fruits. Others in this group (eg, *Gluconobacter*) may cause problems by producing haze and by oxidizing glucose to gluconic acid in soft drinks. Improvements in handling and bottling technologies have resulted in significant reductions in residual oxygen levels such that problems caused by these strict aerobes have become uncommon.[53]

Most of the microaerophilic *Campylobacter* species grow optimally between 40° and 42°C and not below 30°C. *Arcobacter* species and some campylobacters

Table 2-3 Food Poisoning Microorganisms of Major Concern

Minimum Growth Temperature	*Heat Resistance*	
	Low[*]	*High*[†]
Low (0°–5°C or so)	*Listeria monocytogenes* (INF)[‡] *Yersinia enterocolitica* (INF) *Aeromonas hydrophila* (INF)	*Clostridium botulinum* E and nonproteolytic B (TOX)[§] *Bacillus cereus* (INF and TOX) *B. subtilis* (TOX) *B. licheniformis* (TOX)
Medium (5°–10°C or so)	*Salmonella* species (INF) *Vibrio parahaemolyticus* (INF) *Escherichia coli* enteropathogenic and verocytotoxigenic strains (INF) *Staphylococcus aureus* (TOX)	
(10°–15°C or so)		*Clostridium botulinum* A and proteolytic B (TOX) *Clostridium perfringens* (INF)
High (over 30°C)	*Campylobacter jejuni* and *C. coli* (INF)	

[*] In excess of a 6-log inactivation of vegetative microorganisms by pasteurization, eg, at a temperature of about 70°C for 2 minutes.

[†] In excess of a 6-log inactivation of spores at temperatures ranging from about 90°C for most heat-sensitive types to about 120°C for 10 minutes for the most heat-tolerant types.

[‡] INF: organisms that may contaminate foods and may multiply in them, and which cause food poisoning by infection.

[§] TOX: organisms that may contaminate foods and multiply in them to form toxins that then cause food poisoning by intoxication.

are unable to grow at 40°C and may multiply below 25°C.[9,91]

2.2.2 Gram-negative, Catalase-Positive, Oxidase-Negative Rods

The fermentative organisms in this group include the enterobacteriaceae which, apart from the important pathogenic species, contain others that commonly contaminate and grow on many raw foods, particularly if they are stored warm. However, some, such as many of the *Erwinia carotova* group, that characteristically cause plant diseases (eg, soft rots, wilts, and necroses), can grow at temperatures down to about 5°C. As a group, these organisms are not characterized by particular resistance to any of the environmental extremes typical of some food preservation procedures.

2.2.3 Gram-positive, Catalase-Positive, Nonsporing Rods

The corynebacteria, which include more than 30 species, are often pleomorphic, with granulated and club-shaped cells. Many are mesophilic and normally inhabit the skin of man and other animals. However, some that are psychrotrophic are common on plant materials, so that they usually contaminate vegetables and other foods. Their relative tolerances to some preservatives, such as sulfite, encourage the dominance of some members of this group (eg, *Brochothrix thermosphacta*) in the spoilage flora of products such as UK breakfast sausage. Resistance to carbon dioxide, and the ability to grow in low-oxygen environments, encourages the growth of organisms of this group in modified atmosphere and vacuum packed, chill-stored meat.[15]

2.2.4 Gram-positive, Catalase-Positive Cocci

The Gram-positive cocci include many organisms that are commensal on the skins of animals, and are therefore widespread. The aerobic micrococci and facultatively anaerobic staphylococci are often found together in milk products and, being a generally salt-tolerant group, tend to be selected in high-salt cured meat products. In vacuum- or oxygen-free modified atmosphere packs, the micrococci may be

Table 2-4 Food Spoilage Microorganisms of Major Concern

	Microorganisms	
Characteristics	*Examples*	*Foods Typically Affected*
Gram-negative, catalase-positive, oxidase-positive rods	Obligate aerobes: *Pseudomonas, Alkaligenes, Moraxella, Alteromonas, Flavobacterium*	Protein-rich foods (fish, meat, poultry) and vegetables at chill temperatures
	Shewanella, Photobacterium	Fish
	Acetobacter, Acetomonas	Alcoholic beverages
	Gluconobacter	Soft drinks
Gram-negative, catalase-positive, oxidase-negative rods	Fermentative: Enterobacteriaceae, *Escherichia, Citrobacter, Klebsiella, Erwinia, Proteus* Nonfermentative: *Acinetobacter, Xanthomonas*	Most raw proteinaceous foods of animal and plant origin
Gram-positive, catalase-positive, nonsporing rods	Coryneform bacteria: *Corynebacterium, Kurthia, Arthrobacter, Brochothrix*	Cured meats and sausages Fresh meats in vacuum or low-O_2 "modified atmosphere" packs Vegetables
Gram-positive, catalase-positive cocci	Aerobes: *Micrococcus* Facultative anaerobes: *Staphylococcus*	Milk products Cured meat products, especially if high salt
Gram-positive, catalase-negative nonsporing rods	Facultatively anaerobic, homofermentative, and heterofermentative species of *Lactobacillus*	Milk and milk products, fermented dairy, meat and vegetable foods, meat in vacuum, raised CO_2, and/or low-O_2 packs
Gram-positive, catalase-negative cocci	Facultatively anaerobic lactic acid bacteria: *Streptococcus, Lactococcus, Enterococcus Leuconostoc, Pediococcus*	Cured meats, particularly if low salt Dairy products
Gram-positive, catalase-positive, spore-forming rods	Aerobic or facultatively anaerobic species of *Bacillus*	Heated foods with pH values above about 4
Gram-positive, catalase-negative, spore-forming rods	Strictly anaerobic species of *Clostridium*	Heated foods with pH values above about 4.5 (4 for *C. butyricum*) and with restricted availability of oxygen
Yeasts	Mostly facultative anaerobes: *Saccharomyces, Candida, Zygosaccharomyces, Torulopsis*	Low pH and low a_w foods (drinks, jams) whether or not oxygen is excluded
Molds	Mostly strict aerobes: *Penicillium, Aspergillus*	Low pH and low a_w foods exposed to air

Source: Reprinted from N.J. Russell and G.W. Gould, Factors Affecting Growth and Survival, in *Food Preservatives*, N.J. Russell and G.W. Gould, eds., p. 8, © 1991, Aspen Publishers, Inc.

suppressed, but some may utilize nitrate as an alternative to oxygen as an electron acceptor and, therefore, continue to grow under these conditions in nitrate-containing foods. Staphylococci will be selectively encouraged if storage is well above normal chill temperatures. Some strains are sufficiently thermoduric to survive commercial procedures for milk pasteurization. *Deinococcus* and *Deinobacter* species are unique in being more radiation resistant than bacterial spores.[72] *Deinococcus radiodurans* is one of the most radiation-resistant bacteria known and is also relatively resistant to low a_w conditions. It was originally isolated from irradiated ground beef. Of the three other species in this genus, *D. radiopugnans* was isolated from irradiated haddock, *D. radiophilus* from irradiated Bombay duck, and *D. proteolyticus* from llama feces.[71] The only species of *Deinobacter, D. grandis*, was isolated from elephant and carp feces.[81] While surviving most of the low dose applications of radiation that are currently employed, these organisms have not proved to be a problem in current food irradiation practice.

2.2.5 Gram-positive, Catalase-Negative, Nonsporing Rods and Cocci

The lactic acid bacteria are characterized by their homofermentative or heterofermentative modes of metabolism, with the production of lactic acid and consequent souring, or souring plus the formation of gas, in spoiling foods. They are widespread, particularly in the flora of fermentable natural materials such as milk, fruit juices, vegetables, and silage. They often tend to be enriched in foods in which the Gram-negative floras mentioned above (Sections 2.2.1 and 2.2.2) have been inhibited, eg, by the removal of oxygen, by an increase in carbon dioxide, or by a slight reduction in water activity. They are generally more tolerant of low pH than other spoilage bacteria, some continuing to multiply at pH values as low as 3.6. Lactic acid bacteria are common beer spoilage organisms.[53] Some pediococci are extremely salt tolerant. Growth of lactic acid bacteria in many foods is often organoleptically acceptable. They may sometimes play an important "fail-safe" role, ensuring that in foods stored incorrectly, particularly too warm for too long, the pH falls, preventing the growth of more undesirable microorganisms.[49]

2.2.6 Gram-positive, Catalase-Positive, Spore-Forming Rods

The *Bacillus* genus contains 48 species, including psychrophiles, mesophiles, and thermophiles.[11] The primary habitat of most *Bacillus* species is the soil. From there they become widely disseminated in the air and in dust and readily gain access to unprotected foods. Psychrotrophic, mesophilic, and thermophilic members of the genus produce spores that have low, medium, and high heat resistances, respectively (eg, *D*-values of a few minutes at about 80°C for some of the psychrotrophs, at about 100°–120°C for many of the mesophiles, and at well above 120°C for some of the thermophiles, such as *Bacillus stearothermophilus*). They include some strict aerobes, but also facultative anaerobes, so that they are capable of growth in foods in all forms of packaging. Their ability to sporulate ensures that they are of most concern in heated, cooked, or pasteurized foods, particularly if the pH is well above 4, since only a few can grow at pH values this low (eg, *Bacillus coagulans*, at about pH 3.8).

2.2.7 Gram-positive, Catalase-Negative, Spore-Forming Rods

The strictly anaerobic *Clostridium* genus contains over 90 species and, like *Bacillus*, includes thermophiles, mesophiles, and a small number of important psychrotrophs.[17,18] Many clostridia are highly proteolytic and therefore they putrefy food. However, there are important exceptions such as *C. butyricum* and *C. tyrobutyricum*, which cause spoilage by producing low odor threshold acids, and psychrotrophic strains of *C. botulinum*, which are highly saccharolytic. The thermophiles include some of the most heat-resistant spores known (eg, *Clostridium thermosaccharolyticum*). Like the thermophilic *Bacillus* species, these can cause spoilage of thermally processed foods distributed in hot climates unless specially increased heat processing has been applied or nisin has been included to prevent the outgrowth of surviving spores.[34]

2.2.8 Yeasts and Molds

The yeasts[23,32] and molds[31] are major spoilage organisms predominantly in low water activity foods (eg, jams, syrups, dried foods with insufficiently lowered water activities, dried/cured meats, and fish) and in foods in which the pH is low (eg, fruits) or pH has been reduced to levels below about 3.8 (eg, in pickles and marinaded products), because they are extremely tolerant of these two factors. Additionally, some yeasts, eg, *Zygosaccharomyces bailii*, are extremely resistant to weak acid preservatives such as sorbate and benzoate.

While many spoilage yeasts will grow in the presence or absence of oxygen, molds are generally inhibited in oxygen-free packaged foods and are more sensitive than yeasts to carbon dioxide. However, the levels of oxygen necessary to completely suppress mold growth may be very low and difficult to achieve under practical conditions unless some form of oxygen scavenger is employed. Some molds may continue to grow slowly and degrade even hermetically sealed foods. For example, *Byssochlamys* and *Talaromyces* species, which produce relatively heat-resistant ascospores (*D*-values of about 5 minutes and up to 200 minutes, respectively, at 80°C[29]), are able to grow at low oxidation-reduction potential (Eh) and cause liquefaction of pasteurized fruits or pickled vegetable products packed in cans or glass jars.

2.3 PRESERVATION AND SHELF LIFE EXTENSION

2.3.1 Basis of Food Preservation

First, food preservation is based on the delay or prevention of growth of food poisoning microorganisms and the spoilage types summarized above. It must therefore operate through those factors that most effectively influence the growth and survival of microorganisms, including freezing, storage at refrigeration temperatures, and the addition of preservatives. There are over 3,500 additives used in foods, many of which are derived from animal and plant materials. The additives include antioxidants, colors, emulsifiers, stabilizers, sweeteners, flavors, and preservatives. Relatively few types of additives are listed as preservatives. Additives listed as acidulants may also have preservative effects. Before additives are approved they must undergo extensive testing and evaluation to ensure that they are efficacious and toxicologically safe and to ensure that the incidence of allergic reaction is low (as low as between 3 and 15 people per 10,000, which is a lower incidence than allergic reactions to foods such as strawberries and shellfish). Most categories of additives, including preservatives, require approval by relevant regulatory authorities,[88] eg, in European Union (EU) countries[6] and in the United States,[7] a distinction is made between additives classified as GRAS (generally regarded as safe), prior-sanctioned, permanent, or permitted only on an interim basis.

Preservation factors include a number of physical factors, some chemical and some microbiological, ie, they depend on the nature of the microorganisms that are present. These factors have been categorized in a number of ways, but the categorizations that are most widely quoted[50,51,73] separate them into the following groupings (Table 2-5):

- ***Intrinsic factors,*** which include physical and chemical factors that are *within* a food, and with which a contaminating microorganism is therefore inextricably in contact.
- ***Processing factors,*** which include factors that are deliberately applied to foods in order to achieve improved preservation.

Table 2-5 Major Factors Affecting Microbial Growth and Survival in Foods

Intrinsic Factors				
Chemical	*Physical*	*Processing*	*Extrinsic Factors*	*Implicit Factors*
Nutrients	a_w, ERH	Changes in food composition	ERH during storage	Microbial growth rates
pH and organic acids buffering	Ice and freeze concentration	Changes in types of microorganisms	Temperature during storage	Synergistic effects (food components, microorganisms)
Oxidation-reduction potential	Changes in structure	Changes in numbers of microorganisms (heat treatments, irradiation)	Oxygen level, presence of other gases (CO_2 specifically)	Antagonistic effects (food components, microorganisms)
Antimicrobial substances	Changes in microstructure (emulsification)			

Note: a_w, water activity; ERH, equilibrium relative humidity.

Source: Data from D.A.A. Mossel, Essentials and Perspectives of the Microbial Ecology of Foods, in *Food Microbiology: Advances and Prospects, Society for Applied Bacteriology Symposium Series No. 11*, T.A. Roberts and F.A. Skinner, eds., pp. 1–45, © 1983, Academic Press, and D.A.A. Mossel and M. Ingram, The Physiology of the Microbial Spoilage of Foods, *Journal of Applied Bacteriology*, Vol. 18, pp. 232–268, © 1955, Society of Applied Microbiology.

- ***Extrinsic factors,*** which include factors that influence microorganisms in foods, but which are applied from *outside* the food and act during storage.
- ***Implicit factors,*** which include factors that are related to the nature of the microorganisms themselves, and to the interactions between them and with the environment with which they are in contact during growth.

To the above factors Mossel[73] additionally recognized:

- ***Combination effects*** (net effects), which take into account the fact that many of the factors strongly interact so that the overall effects of combinations of factors may not be readily predictable.

Potentially useful combination effects are increasingly derived from modern predictive modeling studies in which the effects of combinations of factors provide most of the data from which mathematical models are derived.[67–69]

2.3.2 Major Food Preservation Technologies

The major technologies employed to preserve foods are all based on a relatively limited set of factors, so that their range is necessarily limited also. The technologies are summarized in Exhibit 2-2 to highlight the fact that most of the techniques act primarily by slowing down, or in some cases completely arresting, microbial growth.

Exhibit 2-2 Major Existing Technologies for Food Preservation

Techniques that slow or prevent the growth of microorganisms
- Reduction in temperature
  —chill storage, frozen storage
- Reduction in water activity
  —drying, curing with added salt, conserving with added sugar
- Reduction in pH
  —acidification (eg, use of acetic, citric acids, etc), fermentation
- Removal of oxygen
  —vacuum or modified atmosphere packaging
- Modified atmosphere packaging
  —replacement of air with CO_2, O_2, N_2 mixtures
- Addition of preservatives
  —inorganic (eg, sulfite, nitrite)
  —organic (eg, propionate, sorbate, benzoate, parabens)
  —bacteriocin (eg, nisin)
  —antimycotic (eg, natamycin)
- Control of microstructure
  —in water-in-oil emulsion foods

Techniques that inactivate microorganisms
- Heating
  —pasteurization
  —sterilization

Techniques that restrict access of microorganisms to products
- Packaging
- Aseptic processing

Source: Copyright © 1989, G.W. Gould.

2.3.3 New and Emerging Food Preservation Technologies

The newer and still-developing techniques include more natural approaches, eg, modified atmosphere packaging, use of "protective cultures," and use of bacteriocins, other culture products, and enzymes (Exhibit 2-3). It is interesting that, in contrast to the more traditional techniques, most of the newer ones that are being explored act by inactivation, eg, irradiation; the application of high hydrostatic pressure; high voltage electric discharge (electroporation); ultrasonication combined with increased temperature and slightly raised pressure (manothermosonication); and addition of bacteriolytic enzymes (eg, lysozyme; Exhibit 2-3).

2.4 COMBINATION PRESERVATION TECHNIQUES

The major preservation techniques that prevent or delay microbial growth are reduction in temperature, reduction in pH value, reduction in water activity, and the application of heat, which inactivates microorganisms. However, these and other techniques are increasingly used together in combination or "hurdle " technologies[59,60,90] (Chapter 14). It is widely expected that these approaches will find increasing future application. While the development of many of the most-used combinations in the past was empirical and traditional in different regions of the world, the basis of their efficacy has been uncovered in some instances, as illustrated below, and this is leading to a more rational approach to preservation.

2.4.1 Low pH–Weak Acid Synergy

Among the most widely used traditional preservation treatments are those in which an antimicrobial

Exhibit 2-3 New and Emerging Technologies for Food Preservation

Natural additives
- Animal-derived antimicrobials
  - —lysozyme
  - —lactoperoxidase system
  - —lactoferrin, lactoferricin
- Plant-derived antimicrobials
  - —herb and spice extracts
- Microbial products
  - —nisin
  - —pediocin
  - —other bacteriocins and culture products

Physical processes
- Gamma and electron beam irradiation
- High voltage electric gradient pulses (electroporation)
- High hydrostatic pressure
- Combined ultrasonics, heat, and pressure (manothermosonication)
- Laser and noncoherent light pulses
- High magnetic field pulses

acid is used as an additive or generated by fermentation, and its effectiveness is enhanced by lowering the pH value. Indeed, the majority of the useful food preservatives fall into this category. A few wide-spectrum food preservatives remain, which are effective at pH values near neutrality (Table 2-6; Chapter 9). The acids include the inorganic preservatives, sulfite and nitrite, and the weak organic acids. The organic acids generally increase in effectiveness in the order acetic, propionic, sorbic, benzoic (Chapter 8), and this reflects their increasing lipophilicity. This gives a clue to one element of their modes of action, because it is the lipid solubility, mainly of their undissociated forms, that enables them to cross the microbial cell membrane and gain access to the cytoplasm within the cell[13,14] (Chapter 8).

The second element important in their modes of action is the dissociation constant of the acid, because it is the undissociated form that is most lipophilic and, therefore, most readily permeates the membrane. The pH value and the dissociation constant determine the proportion of acid that is in this form. The p*K* values of the common weak acid preservatives range from 4.2 (benzoic) to 4.87 (propionic), so that at pH values much above these, antimicrobial activity is much reduced (Chapter 8). At the pH values of most foods, microorganisms maintain an internal pH that is higher than that of their surroundings. On entering the cytoplasm, the undissociated acids therefore tend to dissociate into hydrogen ions and the particular anion. The additional hydrogen ion may be exported by the cell to maintain the high internal pH, but this is energy demanding so that cell growth may be restricted. If the en-

Table 2-6 Most-Used Food Preservatives

Preservatives	*Examples of Foods in Which They Are Used*
Weak lipophilic organic acids and esters	
Sorbate	Cheeses, syrups, cakes, dressings
Benzoate	Pickles, soft drinks, dressings
Benzoate esters (eg, methyl, propyl)	Marinaded fish products
Propionate	Bread, cakes, cheese, grain
Organic acid acidulants	
Acetic, lactic, citric, malic, etc	Acidulants for low pH sauces, mayonnaises, dressings, salads, drinks, fruit juices, and concentrates
Mineral acid acidulants	
Phosphoric, hydrochloric	Acidulants, as above
Inorganic anions	
Sulfite (SO_2, metabisulfite)	Fruit pieces, dried fruits, wine, meat (sausages)
Nitrite	Cured meats
Antibiotics	
Nisin	Cheese, canned foods
Natamycin (pimaricin)	Soft fruit, dry-cured meats
Smoke	Meats and fish

Source: Reprinted from N.J. Russell and G.W. Gould, Factors Affecting Growth and Survival, in *Food Preservatives*, N.J. Russell and G.W. Gould, eds., p. 19, © 1991, Aspen Publishers, Inc.

ergy demand is greater than that available, the pH of the cytoplasm will eventually fall to a level that is too low for growth to continue. In addition, careful uptake studies have shown that a minor part of the preservative actions of some of the acids, and of sorbic and benzoic in particular, results from effects additional to the membrane gradient-neutralizing ones mentioned above,[28] and from membrane dissipation effects that may be indirect (Chapter 8).

There is an important, rational, and practical conclusion to be drawn. Whenever possible, microbial growth is best prevented by simultaneous reduction of pH and the presence of a weak acid preservative and, because there is then an increased energy demand on the cell, by anything additional that restricts the efficient generation of ATP. Examples include the application of further energy-demanding stresses, and, for facultative anaerobes, the removal of oxygen in vacuum or modified atmosphere packages.

2.4.2 Modified Atmosphere Packaging Plus Chill Storage

Carbon dioxide is a weak acid that is widely used as a food preservative in some countries[30] (Chapter 10). When added to a hermetically sealed foodpack, it dissolves and comes into equilibrium within the food to form mainly bicarbonate anion and other chemical species according to the partial pressure of the gas, its relative volume, and the pH and buffering capacity of the food. The efficacy of carbon dioxide results from a number of unrelated phenomena. The elimination of oxygen found in some forms of modified atmosphere packaging alters the spoilage flora by preventing the growth of strict aerobes and slowing the growth of facultative anaerobes by restricting the amount of energy they can obtain from substrates. However, carbon dioxide has a strong specific antimicrobial action, which is very microorganism specific. For example, many oxidative Gram-negative bacteria such as species of *Pseudomonas* are sensitive to concentrations as low as 5%, while many lactic acid bacteria and yeasts are capable of growth in the presence of 100%, and even in carbon dioxide under pressure. Carbon dioxide-enriched packaging of foods such as fresh meats usually results in a shift of the spoilage flora from a rapidly growing Gram-negative to a slower growing Gram-positive association of strains.[22] In modified atmosphere packaged fresh fish, in contrast, the Gram-negative *Photobacterium phosphoreum* is very carbon dioxide tolerant and may therefore be selected as the dominant spoilage organism.[20]

Good low temperature control is vital for effective use of modified atmosphere packaging because the antimicrobial efficacy of carbon dioxide is *greatly* enhanced as the temperature is reduced. While the reasons for the synergism, deriving from the combination of CO_2 with low chill temperature, are not fully understood they probably include the increase in solubility of carbon dioxide that accompanies reduction in temperature.

In addition to the antimicrobial effects of modified atmosphere packaging, there are often important additional effects of the combination technique on food color. These effects together contribute to the useful extension of organoleptically acceptable shelf life. For instance, in the preservation of chill-stored fresh meat, carbon dioxide is usually employed at a concentration of 20% to 30%, with oxygen making up the remainder. While the raised level of carbon dioxide delays growth of the Gram-negative spoilage flora, the raised level of oxygen ensures that the haem pigments remain in the bright red oxymyoglobin form, which keeps the meat looking attractive to the purchaser and doubles the overall chill shelf life.[82]

2.4.3 Low Water Activity Plus Adjuncts

Reduction of water activity to values between about 0.65 and 0.86–0.90 in *intermediate moisture foods* (IMF), prevents the growth of most spoilage bacteria, depending on the pH value[61] (Chapter 7). However, many osmotolerant yeasts and molds multiply at these low water activities so that IMF are not inherently stable by means of their low water activities alone. However, addition of antimycotics, such as sorbic or benzoic acids, provides combinations that can control the osmotolerant fraction of the potential spoilage flora, resulting in long ambient shelf life, as in many semi-moist pet food products. However, these combination systems are less widely used for the preservation of human foods because of the organoleptic penalties resulting from the extensive drying or the high levels of solutes needed to sufficiently reduce the water activity. For this reason, combinations of reduced water activity and other adjuncts, including mild heating, have been successfully developed, because higher water activities, and therefore higher moisture levels and/or lower concentrations of solutes, may be used (Section 2.4.4).

2.4.4 Heat Plus Reduced Water Activity

Mild heating may inactivate nonspore forms of microorganisms in foods and injure surviving spores at temperatures well below those necessary for sterilization (Chapter 3). Lowered water activity is one of many potentially useful synergies of heat with other stresses that may be imposed on microorganisms in foods.

At pH values of 4.5 and above, a "botulinum cook" would normally be required to ensure the safety of long ambient shelf life products, unless some other inhibitory factor was known to be operating (Chapter 3). In particular, in some cured meat products, such an additional factor is low water activity, sometimes with a reduction in pH value and the addition of nitrite. These combination preservation systems allow the production of a wide variety of so-called shelf-stable products (SSPs), which have long, safe ambient stability, and yet require only pasteurization heat treatments.[58,59] The best-known examples include meat products of the Italian Mortadella type. Many other alternative water activity–pH–mild heat process combinations have been reported. Some are employed empirically around the world (Chapter 14), but many others remain unexploited.

2.4.5 Heat Plus Reduced pH Value

The synergy of low pH with mild heating is the basis of the thermal processing of high acid foods, in which the pH, below 4.5, is low enough to prevent growth from spores of *Clostridium botulinum*. However, other mild heat–low pH combination treatments with potential for the preservation of long ambient shelf life foods have been described, though little used. For example, it has been shown that mild heating of spores at low pH values decreases their resistance to subsequent heating, even if the subsequent heating is at a higher pH value.[4] This occurred with all types of spores tested, including *C. botulinum*. It was proposed as a potentially useful procedure for reducing heating requirements for the sterilization of long ambient shelf life foods, but difficulties in designing suitable large-scale processes were such that the acid sensitization procedure has not been used commercially. The mechanism of the effect is partially understood. During the acid heating, hydrogen ions replace some of the spore-bound calcium and other cations to form so-called "H-form" spores, which have reduced tolerance to heat. The procedure is so efficient that virtually all of the calcium, which makes up about 2% of spore dry weight, can be removed from the spores of some species, eg, *Bacillus megaterium*, by this means.[65] When the pH is raised, re-equilibration occurs as hydrogen ions in the spore are replaced again by cations from the food. This process is sufficiently slow enough that heating can be performed while the spores are still relatively heat sensitive. With the advent of modern aseptic processing and packaging techniques for pumpable liquid foods, this sequential combination acid sensitization process would be easier to apply than when it was first proposed.

2.4.6 Mild Heating and Chill Storage

There has been a recent expansion in the use of the combination of mild heating of vacuum packaged foods with well-controlled chill storage, particularly for catering, but also retail. These foods have been termed refrigerated processed foods of extended durability (REPFEDs)[77,78] and include "Sous Vide" products (foods mildly heated within vacuum packs).[62] While the new processes deliver high quality products, they also present new challenges regarding the ensurance of microbiological quality and safety.[66] The success of the procedures results primarily from the inactivation of the vegetative microbial flora by the mild heating, and also from the fact that the spores of psychrotrophic bacteria, which can grow at low chill temperatures, are generally more heat sensitive than the spores of mesophiles and thermophiles, which cannot grow at these temperatures (Chapter 5). The minimal heat treatment necessary to inactivate psychrotrophic vegetative pathogens is generally accepted to be 70°C for 2 minutes[36] or 72°C for 2 minutes[76] or equivalent, to achieve a 6- or 8-log reduction in numbers, respectively, of *Listeria monocytogenes*. The mild heating destroys the vegetative pathogens and the cold-growing fraction of the potential spoilage flora, while the minimal thermal damage and often conditions of low oxygen tension ensure high product quality. If temperatures can be maintained below 3°C, shelf life can be long. To ensure safety if storage temperatures are above 3°C but below 10°C, more severe heat processes are necessary to ensure inactivation of spores of pathogenic spore formers (eg, in excess of 6-log inactivation of spores of psychrotrophic strains of *Clostridium botulinum*,[63,64,76,78] or some form of demonstrable intrinsic preservation of products is generally regarded to be necessary[2,5,45] (Chapter 41).

2.4.7 Heating Following Irradiation

Ionizing irradiation sensitizes bacterial spores to subsequent heating, though the converse is much less effective.[38] The magnitude of the effect varies with irradiation dose rate and is increased if the spores are additionally preincubated at low pH values, as described above. It has been suggested, but not proven, that the effect derives from radiation-induced decarboxylation of peptidoglycan in the spore cortex, which is known to play a role in maintainance of the low water content in the enclosed spore protoplast. In support of this idea, it was shown that the heat sensitizing effect of irradiation was reversed when the treated spores were suspended in solutions of high osmolality before they were heated. It was proposed that this removed water from the partially rehydrated spore protoplast by osmosis, so returning it to the original fully heat-resistant state.

Should the irradiation of foods continue to expand, the synergism of this combination system may be worth reexamination as a practical means for reducing thermal processing requirements and for minimizing heat damage to the nutritional and organoleptic properties of some foods, while retaining long, safe ambient shelf life. The synergism has already been shown to be of practical use in reducing the heat resistance of the spores of thermophilic bacteria in irradiated spices that are subsequently used as ingredients in thermally processed foods.[54] Legal restriction of radiation doses to <10 kGy in most countries that allow food irradiation has prevented the use of some such synergies except for some specific food ingredients (eg, herbs, up to 30 kGy in the US[93] (Chapter 4). However, recent World Health Organization (WHO) and International Atomic Energy Agency (IAEA) recommendations, which state that there should be no upper dose limit for the treatment of food with ionizing radiation, may encourage a reexamination of the potential benefits of combination techniques.

2.4.8 High Pressure Synergy with Mild Heat

With regard to the pressure sensitivity of microorganisms, an important division exists between the vegetative and the spore forms of bacteria. While many environmental factors greatly affect pressure tolerance (in particular the water activity[80,89]), the generalization still holds that vegetative forms are inactivated by pressures in the region of 300 to 500 MPa but spores of some species resist pressures well in excess of 1,000 MPa. For this reason, most current applications of high pressure technology for food preservation are for low pH foods in which spores are not a problem because, even if they survive, they are unable to grow (Chapter 13).

However, there is a strong synergism of pressure with heat such that the spores of some species can be inactivated, even at pressures as low as 100 or 200 MPa, if the pressure is raised at the same time as the heat is applied. The basis for the efficacy of this combination treatment is partly explained by the fact the pressure in this intermediate region can directly cause spores to germinate.[19] Having germinated, they are then sensitive to heat, and also to pressure if it is high enough. While the required pressure-heat combinations are currently too extreme for wide commercial application for the sterilization of high water activity-high pH foods, the addition of other adjuncts (hurdles) may well introduce a new series of pressure combination procedures that are effective for long shelf life food preservation in the future. Presumably, any such novel procedure would have to achieve at least a 12-log kill of spores of *C. botulinum*, and other pathogenic spore formers, to match the accepted safety levels for thermally processed foods.[40]

2.4.9 Ultrasonication with Pressure and Mild Heat

While high intensity ultrasonic radiation has been known for many years to inactivate vegetative forms of bacteria, yeasts, and molds by their physical destruction resulting from the effects of cavitation, spores are known to be much more resistant. Synergism of ultrasonic waves with hydrogen peroxide[3] and with heat[79] have been described. However, application of ultrasonic energy with heat and with a slightly raised hydrostatic pressure together (manothermosonication) has more recently been shown to be an effective combination that effectively reduces, by about 10°C or more, the temperature of heating necessary to achieve a particular kill of vegetative cells and of spores.[85] While the detailed mechanism by which inactivation of the microorganisms occurs is not known, the physical basis is thought to include the effect of pressure on the vapor pressure of water. This increases the effectiveness of cavitation and, in particular, reduces the fall off in cavitation efficiency that normally accompanies a rise in temperature (Chapter 13).

Currently, manothermosonication is laboratory or small-pilot scale, but may well have future potential as an alternative pasteurization or sterilization method for liquid foods. Its application for solid foods is less likely because of the difficulty of economic delivery of sufficiently high ultrasonic intensities into solid substrates.

2.4.10 High Voltage Electric Discharge

Substantial inactivation of vegetative cells of bacteria, yeasts, and molds can be achieved by delivering pulsed electric discharges to liquid foods.[87] A major part of the mechanism of action is the puncturing of the cell membrane at the poles of the cell with respect to the voltage gradient.[86] This damage occurs because, at the high voltage gradients used, a potential difference of about 1 volt or more becomes applied across the cell membrane, which represents an enormous voltage gradient. The technique therefore acts by breaching one of the most important cell structures involved in many key homeostatic mechanisms, eg, control of cytoplasmic pH, maintenance of chemiosmotic ion gradients, and operation of osmoregulation mechanisms (Chapter 13).

2.4.11 Naturally Occurring Antimicrobial Systems

In addition to the more traditional and "emerging" systems employed to achieve desired safe shelf lives, there is consumer pressure for still milder, more natural means for the preservation of foods. This pressure has resulted in concentrated attention on the wide range of extremely effective naturally occurring antimicrobial systems seen in animals, plants, and microorganisms,[44] with the goal of exploiting these systems in foodstuffs[21,25] (Table 2-7).

Animal-derived systems include enzymes such as lysozyme, lactoperoxidase, other proteins such as lactoferrin or lactoferricin derived from lactoferrin by limited proteolysis, ovotransferrin, serum transferrins, small peptides such as histatins and magainins, and even the immune system. Plant-derived systems include phytoalexins, low molecular weight components from herbs and spices, phenolics such as oleuropein from olives, and essential oils. Microorganism-derived systems include organic acids, hydrogen peroxide, diacetyl and other low molecular weight substances, and bacteriocins such as nisin and pediocin and many others discovered in the last few years[1] (Table 2-7 and Chapter 12).

While many of these naturally occurring systems have been described and explored for food use, very few are actually exploited at this time. Only lysozyme, used to prevent defects in some types of cheeses caused by *Clostridium tyrobutyricum*,[16] and nisin,[24] used to help to preserve some cheese products and to protect some canned foods from spoilage by thermophilic spore formers, are in relatively wide use. However, the future potential for application of such systems is substantial as their efficacy is demonstrated in combinations with the other antimicrobial factors and procedures that can already be used to preserve foods.[25]

2.5 CONCLUDING REMARKS

2.5.1 Interference with Homeostasis As a Basis for Improved Food Preservation

While the range of well-established, new, and emerging techniques for food preservation and for

Table 2-7 Naturally Occurring Antimicrobial Systems

Origin	*Example*
Animals—constitutive systems	Myeloperoxidase in phagosomes Transferrins in serum Lactoperoxidase, lactoferrin in milk Lysozyme, ovotransferrin (conalbumin), avidin in eggs
Animals—inducible systems	Antibodies, complement in immune systems Attacins, cecropins in insects Magainins in frogs
Plants—constitutive systems	Eugenol in cloves, allicin in garlic, allyl isothiocyanate in mustard, oleuropein in olives
Plants—inducible systems	Low molecular weight (MW) phytoalexins, high MW polyphenolics in injured or infected plants
Microorganisms	Nisin, pediocin, and other bacteriocins from lactic acid bacteria Antimycotics from fungi (natamycin) Bacteriophages Yeast "killer toxins" Organic acids and other low MW metabolites

achieving a satisfactory shelf life may seem to be diverse, there are two underlying themes that are fundamental to most of the newer, most successful methods. First, from the practical standpoint, many of the techniques are milder and less damaging to product quality and, in reaction to changing consumer requirements, are sometimes more natural than before. Second, from the scientific standpoint, clearly most of the techniques are effective because they overcome the various homeostatic mechanisms that microorganisms have evolved in order to survive extreme environmental stresses (Table 2-8).

There is a logic to many of the combination preservation procedures that are increasingly employed and researched because they act by amplifying this interference with homeostasis.[41] For example, reduction of a_w and pH interferes with macromolecular structure and assemblies and puts extra energy demands on cells, eg, for the maintenance of cytoplasmic pH. Addition of a weak organic acid delivers H^+ into the cytoplasm, further increasing the energy demand. Removal of O_2 then restricts the amount of energy available to perform some of these homeostatic responses, suggesting a rational basis for the efficacy of even such complex combination preservation mixtures as low a_w + low pH + organic acid + vacuum or modified atmosphere packaging.

2.5.2 Stress Responses of Microbial Cells

Many of the preservation systems that act to inhibit microbial growth are effective because they interfere with homeostasis by imposing stresses on microbial cells. However, the cells' responses to stress may result in an increased tolerance to that stress and even to other, apparently unrelated, stresses as well.[33,47,48] In pathogens, the stress response may include an increase in virulence.[70] Naturally occurring strains, eg, *Escherichia coli* and *Salmonella enteritidis*,[57] include a much higher incidence of high-rate mutators than laboratory-attenuated strains. This may lead to enhanced recombination among species and encourage the rapid emergence of antibiotic resistance and the distribution of virulence genes, for example, within the prokaryotic community.[57] Care must therefore be exercised in the development of milder preservation techniques in case situations in which microorganisms more easily, and less safely, overcome the applied stresses.[55] On the other hand, Archer[8] has pointed out that milder preservation procedures may, by delivering less extreme stresses to microorganisms, actually lead to a reduction in microbial stress responses in foods and, therefore, to an improvement in food safety.

Table 2-8 Active and Passive Homeostatic Mechanisms in Microorganisms

Environmental Stress	*Example of Homeostatic Reaction*
Active homeostasis	
Low nutrient levels	Nutrient scavenging, oligotrophy, generation of "viable nonculturable" forms
Low pH, presence of weak organic acids	Extrusion of hydrogen ions, maintenance of cytoplasmic pH, and membrane pH gradient
Reduced water activity	Osmoregulation, avoidance of water loss, maintenance of membrane turgor
Low temperature—growth	Membrane lipid changes, cold shock response
High temperature—growth	Membrane lipid changes, heat shock response
High oxygen levels	Enzymic protection from oxygen-derived free radicals
Biocides and preservatives	Phenotypic adaptation and development of resistance
Ultraviolet radiation	Excision of thymine dimers and repair of DNA
Ionizing radiation	Repair of DNA single strand breaks
Passive homeostasis	
High temperature—survival	Low water content in the protoplast of bacterial spores
High hydrostatic pressure—survival	Low spore protoplast water content?
High voltage electric dicharge	Low conductivity of spore protoplast
Ultrasonication	Structural rigidity of cell wall
High levels of biocides	Impermeable outer layers of cells
Population homeostasis	
Competition	Formation of biofilms, aggregates with some degree of symbiosis

Most of the homeostatic mechanisms employed by microorganisms to overcome the effects of preservation procedures are *active*, ie, requiring changed gene expression and consequent changes in metabolism for their operation. However, some homeostatic mechanisms are *passive*, having been built in to the microbial cell when it was formed, ie, the *refractory homeostasis* of Gerhardt.[37] Low pH sensitizes bacterial spores to heat by overcoming a part of the spores' passive homeostatic resistance mechanism. High hydrostatic pressure and manothermosonication somehow do likewise. Electroporation interferes with all those homeostatic mechanisms that depend on an inbuilt, intact, semipermeable cytoplasmic membrane for their effective operation.[83] Altogether, therefore, interference with homeostasis, particularly by the logical use of combinations of techniques, remains an attractive focus for future work.

Appendix 3-A Definitions

3.1 INTRODUCTION

Heat treatment is used to produce safe and shelf-stable foods such as canned products and to eliminate pathogenic microorganisms, eg, the pasteurization of milk and liquid egg. Commercially canned foods that have undergone a satisfactory heat treatment may contain viable bacteria. For example, acid canned foods with a pH of 4.6 or lower (according to regulations in the United States (US)) or with a pH lower than 4.5 (according to regulations in the United Kingdom (UK)) may contain viable bacterial spores whose ability to germinate and give rise to growth is prevented by the acid pH of the food. Canned low-acid foods may contain spores of thermophilic bacteria that have a very high heat resistance but are unable to germinate and outgrow at temperatures below about 30°C. Such canned foods are stable in temperate climates but may spoil in tropical climates, necessitating either increased heat treatment or the use of antimicrobial additives. The term *commercial sterility* is often used to describe the process endpoint of canned foods. Strictly speaking, this term lacks meaning because sterility implies the absence of living organisms. In the canned foods industry, *commercially sterile* cans have received a process such that, for the specific food storage conditions, the food will neither spoil nor endanger the health of the consumer.[48]

While a patent for the preservation of food by heat was published in 1691 by Procter and White (quoted by Cowell[35]), practical food preservation by heat originated later. In about 1810, Appert demonstrated that heating foods in hermetically sealed containers could render them shelf stable for long periods at ambient temperatures.[7] Over a century later, Bigelow et al.[15]

made the first mathematical evaluation of heat sterilization applied to canned foods, and Ball[8] built on this to derive "methods of calculations for determining the time necessary to process canned foods." Many new approaches have since been proposed,[108] and processes are now set using elegant software programs and delivered by computer-controlled retorts or autoclaves. However, the original studies provide a sound foundation for almost all of the subsequent publications that underpin the modern thermal processing technologies. Even now, the Ball[8] method remains the basis of the methodologies most widely employed in the US, and Ball's method along with the method of Gillespy,[47] remains widely used in the UK.

The goal of thermal processing for commercial sterilization is to deliver sufficient heat to inactivate all of the potential spoilage and pathogenic microorganisms that may be present and capable of growth in a particular food. While this is the ultimate objective, as a result of the inactivation kinetics of microorganisms by heat, a more accurate definition is to reduce the probability of survival and/or growth of microorganisms in a particular food to an acceptably low level. The rationale of what is an acceptably low level has developed over many years and has centered on considerations of safety, following the original studies of Esty and Meyer[42] on the thermal inactivation kinetics of spores of proteolytic strains of *Clostridium botulinum.*

Early studies of the heat resistance of bacterial spores were made in order to develop processes for the production of canned foods. The concept of the *thermal death point* was used and was defined by Bigelow and Esty[14] as "the length of time at different temperatures necessary to completely destroy a definite concentration of spores in a medium of known hydrogen ion concentration." This was determined by sealing a suspension containing a known number of spores into tubes, immersing the tubes in a water bath at the required temperature for given periods of time after which the tubes were cooled rapidly and tested for sterility. Because the measured heat resistance of spores is influenced greatly by the nature of the suspending medium, studies of the resistance of spore crops in a standard phosphate medium at pH 7 were used as a reference prior to determination of their resistance in various foods. Based on a study of 109 strains of *C. botulinum,* Esty and Meyer[42] concluded that for the spores of this organism that showed the maximum heat resistance, heat treatments were necessary to sterilize suspensions containing billions of spores in phosphate buffer at pH 7 as follows: 4 minutes at 120°C; 10 minutes at 115°C; 33 minutes at 110°C; 100 minutes at 105°C; 330 minutes at 100°C. They also showed (1) that at 100°C the log of the number of viable spores decreased by more than 10 log cycles in a roughly linear manner with time of heating, (2) that germination of heated spores could occur after very long delays, and (3) that in juices from some canned foods, the heat resistance of the spores was greater than in the reference phosphate buffer.

Many subsequent experiments have been carried out to determine the heat resistance of spores of *C. botulinum* and *C. sporogenes* in phosphate buffers and in foods. The concepts of *F*-value and *z*-value were introduced, where *F* is the number of minutes required to destroy the organism in a specified medium, at a specified temperature, and *z* is the slope of the thermal death time curve expressed as the interval in temperature required for the line to pass through one log on semi-log paper.[107] The data of Esty and Meyer[42] for *C. botulinum* were recalculated incorporating corrections for heating and cooling lags. The resulting *F*-value for *C. botulinum* in low-acid canned food is 2.45 equivalent minutes at 250.0°F or 121.1°C with a *z*-value of 17.6°F or 9.8°C. This is recognized in the canning industry as the minimum practical *C. botulinum* process.[107] The safety aspects of the application of heat for food product sterilization are still based on these early studies. Esty and Meyer[42] had proposed standards for sterilization based on a reduction of spore populations by a factor of 10^{11} or 10^{12} and Hicks[53] argued that destruction of spores of *C. botulinum* by at least this extent was necessary to ensure the safety of low-acid canned foods. The generally observed efficacy of sterilization processes, and the lack of major problems when the processes are properly carried out, has provided evidence over many years that the basic rationale, however derived, is sound and cautious.[52,74,75,79,103]

The logarithmic death model as a function of a heat process, U, is $U = D(\log N_0 - \log N_U)$. U is the time of heating at a specified temperature, D is the time for a 90% reduction in the number of surviving organisms, N_0 is the initial microbial load, and N_U the endpoint survivor level (see Appendix 3-A for definitions of key terms); in microbial control processes it is a probability value such as 1 in 1,000 or 1 in 10^6 or 10^9. The value n is used to indicate the log-cycle reduction, $n = (\log N_0 - N_U)$, therefore, $U = n \times D$. In the food safety area, $n \times D$ is often used today as the process requirement, though it is a type of process design simplification and may be misleading. For example, a weakness of the $n \times D$ concept is that it only specifies a reduction in microbial load. Ideally, we should specify the endpoint in the microbial control process calculation. The endpoint will be the risk (expressed as a probability) that we are willing to take regarding having the pathogenic agent in a single serving of the food that we consume, but this requires an assumption about the initial numbers of microorganisms present, which is seldom confidently known. Examples of the use of $n \times D$ are: 12*D*, as the required *C. botulinum* process for low-acid canned foods; and 7*D*, to ensure safety with respect to the inactivation of salmonellae during the cooking of meat.[5] This latter use led to a US Department of Agriculture (USDA) requirement for this level of inactivation in the cooking of roast beef, and 5*D* was required for salmonellae in ground beef and *Escherichia coli* O157 in fermented sausages. Similarly, 6*D* processes (UK Department of Health[6]) or 7*D* processes[66] were proposed to ensure safety with respect to the survival of *Listeria monocytogenes* in mildly heated, in-pack pasteurized, chill-stored foods.

The ability to achieve these desired levels of destruction in particular processes depends absolutely on knowledge of the kinetics of heat inactivation of microorganisms in foods. This has been the focus of numerous research and modeling studies.

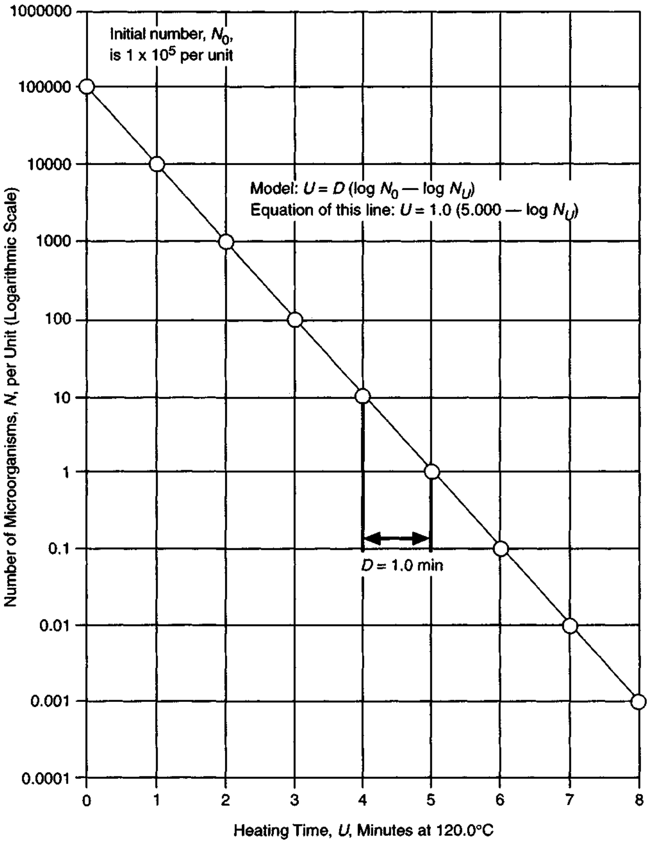

Figure 3-1 Basic Inactivation Kinetics. Microbial survivor data plotted on a semi-logarithmic graph. Number of survivors plotted on a log scale on the y-axis versus heating time on an arithmetic scale on the x-axis. *Source:* Copyright © 1995, I.J. Pflug.

3.2 KINETICS OF DESTRUCTION OF MICROORGANISMS BY MOIST HEAT

3.2.1 The Death Kinetics of One-Celled Organisms

Rahn[88] cited experiments showing that moist heat treatment at constant temperature resulted in a logarithmic rate of death of vegetative microorganisms and spores. Discounting various well-established deviations and artifactual effects that can influence the shapes of survivor curves (see below), the underlying kinetics is such that, when an aliquot of a homogeneous culture of microorganisms is heated at constant temperature, the numbers of survivors, therefore, represent a geometric progression, this condition is recognizable graphically by the straight line obtained by plotting the logarithms of their numbers against the time of exposure. In Figure 3-1, such data are plotted as log N versus heating time. When the logarithm of the number of surviving microorganisms is plotted on an arithmetic scale, as in Figure 3-1, the data points form a straight line and the y-axis is effectively expanded resulting in equal readability at all survival levels. This readability makes these graphs very useful in the microbial control field. The semi-logarithmic graph is immensely useful, but a nondistorted perspective of the effect of a constant stress on a homogeneous population must be kept in mind. This perspective can be obtained when the data in Figure 3-1 are plotted on a graph, with an arithmetic scale on both the x- and y-axes (Figure 3-2).

In the semi-logarithmic survivor curve model, the points on the graph larger than 1×10^0 correspond to survival levels larger than one microorganism per unit and all points less than 1×10^0 have a mean survival level less than one per unit, a fractional microbial survival level. There may be one surviving organism in 10 units, one in 100 units, one in 1,000 units, etc. as we approach zero organisms per unit.

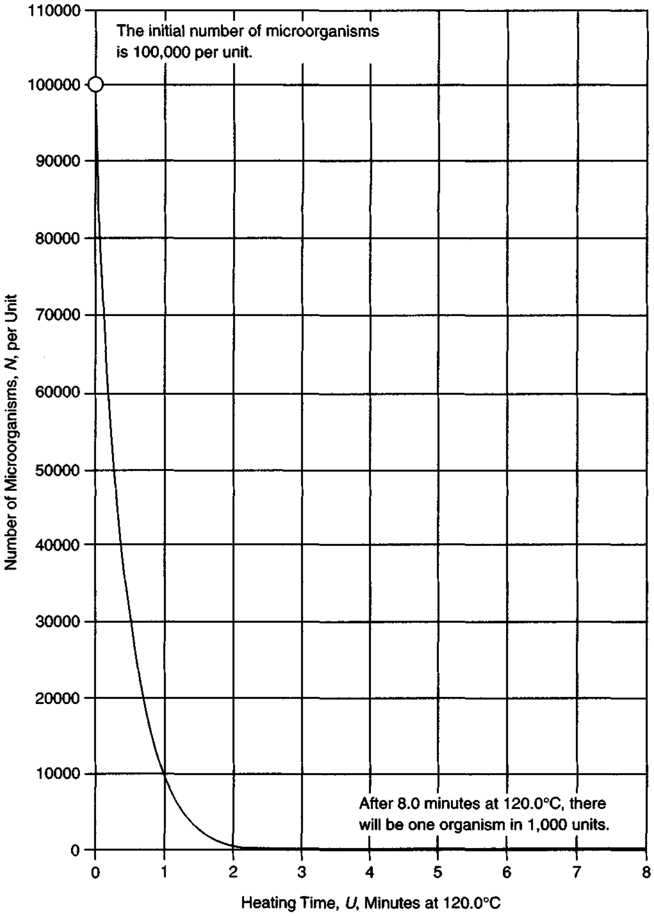

Figure 3-2 Basic Inactivation Kinetics. The same microbial survivor data as in Figure 3-1, plotted arithmetically on the y- and x-axes. *Source:* Copyright © 1995, I.J. Pflug.

These fractional survival levels are small positive numbers, for example, 1 in 10 = 0.1, 1 in 100 = 0.01, 1 in 1,000 = 0.001, etc.; however, their logarithms or exponential powers of 10 are the negative numbers: –1, –2, –3, etc. As we move toward zero survivors per unit, the survival fraction number becomes increasingly small and the negative exponent value increasingly large.

It has thus become customary to speak of "the logarithmic order of death" or the "exponential inactivation" of bacteria. Rahn,[88] however, did state in relation to plots of log survivors against time: "The difference in the order of death between bacteria and higher organisms has occasionally been questioned. A survey of all experiments on the order of death of bacteria until 1930[87] showed that 25% of the curves resembled those of multicellular organisms, 21% were strictly rectilinear, and 54% were concave upwards. Most of the 25% resembling multicellular organisms were actually obtained with 'multicellular bacteria,' ie, the bacteria were clustered. Since that survey, a number of investigations have verified the logarithmic order.[11,12,102,103,115] The difference between bacteria and higher organisms which causes this difference in kinetics of inactivation is the obvious one: with bacteria, the individual is dead when a single cell dies; with higher organisms, the death of one cell does not kill the organism."

The most commonly quoted hypothesis to account for the logarithmic order of death of microorganisms is therefore the thermodynamic one derived particularly by Rahn[88] and others.[26,31,64,75] The principal alternative follows from the proposals of Withell,[118] who pointed out that a distribution of resistances among individual cells in a population could lead to exponential inactivation kinetics if heat was assumed to act equally and uniformly on each cell. This "vitalistic" approach was developed by Cole et al.[34] to model the heat inactivation kinetics of *Listeria monocytogenes.*

The thermodynamic approach is based on the fact that at any instant, in any system at any temperature above absolute zero, there is a distribution of energy levels among the molecules that are present. In order to react with, and inactivate, a target molecule that is within a microorganism and is essential for viability, the energy of the reactant molecule must exceed a certain value. At constant temperature, therefore, individual target molecules in a population will all be subjected to the same *chance* of inactivation per unit time. At constant temperature the kinetics of inactivation will therefore be logarithmic. This is the simplest explanation of classical heat inactivation kinetics. It is attractive because it is soundly based on the true nature of heat. Also, it is important to remember that this simple explanation is necessarily based on some equally simple assumptions. The first (reasonable) one is that there is a distribution of energies among water or other molecules surrounding the "lethal target molecules" in bacterial cells. The second assumption is that all such target molecules have the same (in)activation energies. The third assumption, which is arguable, is that there is only one, or a small number, of such target molecules per cell (otherwise one would expect pronounced "shoulders" on survivor curves due to "multihit" kinetics). The fourth assumption is that substantial repair is not possible, otherwise, as with the inactivation by irradiation of bacteria, which have the capacity to repair damaged DNA, a shoulder would again be expected. With additional artifactual effects, eg, due to clumping of cells in suspension, nonuniform populations resulting from different ages of cells, there are therefore ample opportunities for deviations in practice. However, all are superimposed on the logarithmic order of death, which has a sound theoretical basis.

For example, Moats et al.[64] developed a model for the thermal death of bacteria on the basis that a cell has many critical sites, and that several of these sites must be inactivated before death occurs. The inactivation of individual sites was assumed to take place at random and the inactivation of each site followed first-order kinetics. Prokop and Humphrey[86] described a model for the inactivation of spores during heating that assumed that, following heating, a spore is in one of three sequentially occupied states: heat shocked, heat sensitive, or nonviable. A sequential first-order model was assumed, with sequential reaction rates, K_1 and K_2. (There is no evidence today that heat shock and heat sensitivity are linked.)

Several models for microbial destruction were developed by Brannen.[19] He discussed a multihit model in which nonlogarithmic survival is inherent in the organism. A similar model can be used to obtain all of the shapes of survivor curves shown in Figure 3-3.[18] Brannen[20] also investigated, via models, the consequences of the assumption that the genetic homogeneity and the DNA chemical homogeneity of a microbial population are not equivalent. Frederickson[45] described probabilistic microbial death models similar to those mentioned above. He observed that in such models, the extinction time of the "last" organism is a random variable, and that the modeled survivor curve shows sudden, unpredictable drops as the population size gets smaller. In studies where the logarithmic survivor curve was concave downward, Alderton and Snell[2] used a model in the form $(\log N_0/N)^a = Kt + C$ to analyze their data. Schalkowsky and Wiederkehr[94] developed a model in which they assumed that the incremental death time of heated microorganisms is directly proportional to prior exposure time and concluded that the logarithm of the survival time is normally distributed. They derived the normal distribution for survival times by assuming that prior exposure time does not produce a cumulative effect on the destruction process. Analysis of data showed an early normal distribution followed by a log normal distribution of survival times. The authors therefore indicated that these observations are consistent with the idea that environmental effects are dominant in the early stages, and that time cumulative effects are stronger in the later stages of a lethal stress process. Shull et al.[99] considered a spore thermal death model that obeys first-order kinetics and that has a first-order dormant spore activation component. They described how this model may explain an initial lag period that is sometimes observed in semilogarithmic survivor curves.

Abraham et al.[1] carried out experimental survivor curve studies using *Bacillus stearothermophilus* spores in aqueous suspension at six constant temperatures ranging from 105°–130°C. The survivor curves displayed initial shoulders before log-linear declines. They used their data to test the idea of Shull et al.[99] mentioned above. Mathematical analysis showed that this model could represent not only their experimental survivor curves, but also all other shapes of survivor curves (linear and biphasic) found in the literature. Also, there was an inherent symmetry in the model formulation between the activation and destruction reactions. Abraham et al.[1] showed that the dormancy rate was the only parameter that permitted a distinction between the two reactions. The reaction rate values, K_D-values, were converted to D_T-values, which were plotted on a thermal resistance curve and were well represented by a straight line with a z-value of 8.6°C.

The D-value is one of the most useful tools in quantitative microbiology. It is important to understand and use it properly. In the most basic and accurate sense, the D-value is the cotangent of a line on a graph where data are plotted in the format $\log N$ on the y-axis versus U minutes on the x-axis. Experimental survivor curve data are plotted on a graph of $\log N$ versus stress time U. When the data can be represented by a straight line, a line is drawn through the data points, either freehand or using the parameters obtained from a linear regression analysis of $\log N$ versus U. To indicate the direction of the line, the cotangent instead of the tangent is calculated, and is assigned the symbol, D, for decimal reduction. The cotangent of the line (the D-value) is the time for the line to cross one logarithm. This is also the time for a 90% reduction in the numbers of surviving microorganisms.

Survivor curve data from most homogeneous populations of spores and microbial cultures, gathered under ideal conditions, form straight-line semilogarithmic survivor curves and can therefore be assigned D-values. The D-value reported will always be the D-value for the specific culture of microorganism tested using a specific methodology and recovery medium, etc. Neither the microbial species nor the strain has an intrinsic D-value. For a given species of microorganism, therefore, a range of D-values should be expected from the literature. For example,

B. *stearothermophilus* spores subjected to high temperature moist heat usually have $D_{121.1°C}$-values between 2 and 6 minutes; when *C. sporogenes* spores are tested under moist-heat conditions, they usually have $D_{121.1°C}$-values between 0.5 and 1.2 minutes.

See Casolari[27] for a more in-depth review of microbial death kinetics and models of microbial inactivation.

3.2.2 Graphical Presentation of Microbial Survival

Figure 3-1 shows a straight-line semi-logarithmic survivor curve. In practice, however, when the survivor curve data for apparently homogeneous microbial spore populations subjected to moist heat are plotted on semi-logarithmic graphs, the resulting curves are not always straight lines through N_0, as indicated in Section 3.2.1. Microbial survivor data do not always fit the logarithmic model exactly:

$$\log N = -U/D_T + \log N_0$$

The shape of the survivor curve varies with spore crop, substrate, and test temperature.[82] The most commonly observed survivor curves are shown in Figure 3-3. About 40% of survivor curves are approximate straight lines through N_0, like the curve labeled "a" in Figure 3-3. About 40% of survivor curves are of shapes "b," "c," or "d." The test results of some spore crops, substrates, and test temperatures are semi-logarithmic survivor curves that are sigmoid in shape (eg, "e" in Figure 3-3) or just curves (eg, "d" in Figure 3-3).

The caption to Figure 3-3 summarizes some of the explanations that may explain the various curve shapes. In addition, the medium used to estimate the number of surviving organisms after heat treatment can have a profound effect on the results. For example, the addition of starch, bicarbonate, and other supplements and of lysozyme to a medium can greatly increase the estimated number of spores of some *Clostridium* species that survive heat treatment.[59] The strength of the medium may also have an effect. In some cases, a more dilute medium may recover more heat-injured spores than a more concentrated medium.[121] In commercially prepared media, each batch is identified by a specific lot number and, because many natural ingredients vary, no two lots are the same and different lots from the same manufacturer may differ markedly in their ability to allow growth of heat-treated microorganisms. In a testing program to measure the effect of heat processes on microorganisms, it is essential to use the same media lot number in the evaluation of numbers of survivors in all tests where numbers of surviving microorganisms are to be compared.

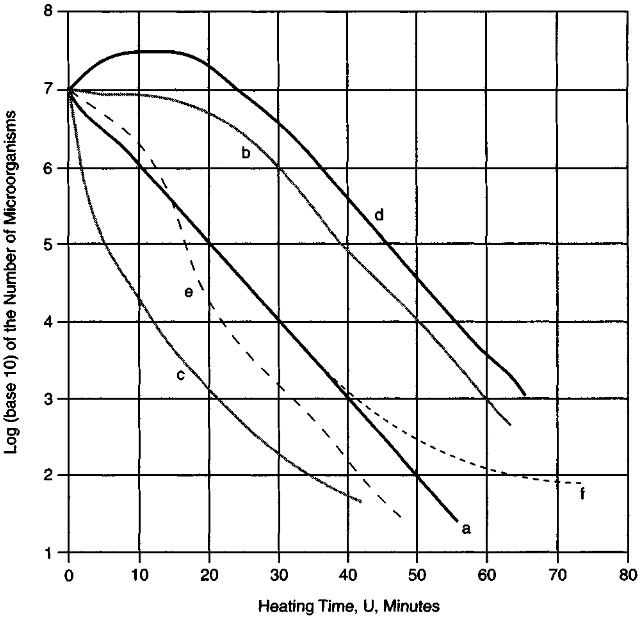

Figure 3-3 Microbial Survivor Curves. The primary shapes of microbial survivor curves (in the form log *N* as a function of heating time) obtained when bacterial spores are subjected to a heat process where the heating time is sufficiently long that heating and cooling errors are minimal: (a) straight-line classical, log linear, constitute about 40% of spore survivor curves, eg, *C. sporogenes* in phosphate buffer[82]; (b) concave downward curves are often described as having a shoulder; "multihit" inactivation processes have been proposed as a cause[64]; also, extensive clumping of cells can result in a delay before numbers of CFU begin to decline; 20% to 25% of survivor curves are this shape; (c) concave upward survivor curves result when there is a mixed microbial population[87]; also homogeneous cultures of microorganisms subjected to dry heat characteristically produce concave upward survivor curves[74]; 20% to 25% of survivor curves are this shape; (d) an initial rise in numbers of CFU prior to exponential decline may result from the need for significant heat activation of the spores before they are able to germinate; (e) combinations of all the above factors often result in sigmoidal-type curves such as the one with the dashed line; (f) classical curve (a) with a tail; tailing often occurs as a result of faulty experimental testing procedures or equipment,[77] or may be artifactual, resulting from the presence of small numbers of large clumps of cells in the population, or from heterogeneity, cell-to-cell differences of heat resistance within the population,[29,98] or even from "heat adaptation," an increase in resistance to heat occurring during the heating process.[50] *Source:* Copyright © 1989, G.W. Gould.

With respect to thermal processing, however, the fitting of a regression line to data forming curves like those illustrated by "d" or "e" in Figure 3-3 cannot be justified, other than to obtain a measure of the general direction of the data. Confidence limits should be indicated on numbers. Statistical aspects of the enumeration of microorganisms are reviewed in Chapter 60. Heat treatment can result in sublethal injury of microorganisms, which affects their ability to form colonies on recovery media (Chapter 15).

Deviations from true exponential survivor curves, similar to those sometimes observed with spores (Figure 3-3), occur to a greater degree and more often for vegetative cells.[3] This is particularly prevalent during lower temperature–longer time treatments when vegetative cells, unlike spores, may continue to metabolize and, thus, change in composition and structure, and consequently in thermal resistance, during the actual heating process. The so-called "heat shock" response (see below) can result in a substantial rise in microbial heat resistance, so that the resulting tails and shoulders on curves can be very pronounced and, again more so than with spores, can be greatly influenced by the heating menstruum and by the conditions of growth prior to heating. For example, Figure 3-4 illustrates survivor curves obtained with *Salmonella typhimurium* pretreated in various ways and heated in different menstrua. The variability illustrates well the difficulty in establishing unique thermal inactivation kinetics for vegetative cells, and the dangers of extrapolating one set of data to different environmental situations. However, it is generally maintained[116] that there is an underlying log:linear relationship on which these deviations are superimposed and, as with spores, similar explanations have been put forward to account for the variety of the shapes of vegetative cell survivor curves. These range from "single hit" models, as discussed above, to the assumption that the survival patterns predominantly reflect inherent phenotypic variations in the susceptibility of the individuals in a population to heat.[3] On this basis, heat is assumed to affect all cells in a completely uniform manner, and the shape of the survival curve is determined solely by nonuniform distribution of heat resistance within the population. Hansen and Reiman[51] assumed as much and concluded that the death of individual cells resulted eventually from accumulated damage.

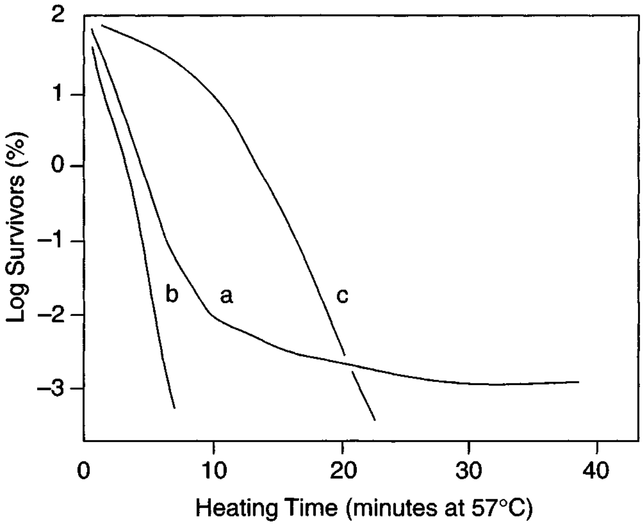

Figure 3-4 Heat Adaptation and the Influence of Heating Menstruum on the Heat Resistance of Vegetative Cells. Inactivation curves of *Salmonella typhimurium* heated at 57°C. Curve a: *S. typhimurium* Tm-1 grown in trypticase soy broth plus yeast extract (TSBY), washed, and heated in ground beef. From Thompson et al.[106] Curves b and c: *S. typhimurium* LT2, grown in TSBY and heated in the same medium without a prior heat shock (b) or following incubation at 48°C for 30 minutes (c).[61] *Source:* Copyright © 1989, G.W. Gould.

More recently, it has become well established that when vegetative cells of microorganisms are subjected to a variety of environmental stresses, including heat, they react homeostatically in such ways as to adapt to the stress. These adaptations involve the activation and expression of new groups of genes, eg, following irradiation,[65] osmotic shock,[17] oxidative stress,[37] starvation,[49,97] etc. The same is true for heat. Mild heating leads to the synthesis of "heat shock" proteins (eg, in *Escherichia coli,*[120] in *Neurospora crassa*[85]), in reactions that are widespread, occurring in all organisms that have been studied so far, including prokaryotes, eukaryotes, and humans.[95] Following synthesis of the new proteins, the heat resistance of cells rises. The rise may be transient, or resistance may remain elevated for long periods, depending on the conditions and on whether the synthesis of the heat shock proteins continues.

The extent to which the synthesis of heat shock proteins, and the consequent thermal adaptation, is important in food preservation and safety is not always obvious. Most of the practical uses of heat, in sterilization and pasteurization procedures, involve relatively rapid heat-up rates so that the opportunity for substantial thermal adaptation does not arise. However, when slow cooking procedures are used, eg, for large-volume cooked meats destined for chill storage and slicing at the point of retailing and for cooking in the home, thermal adaptation may be important in a limited number of cases. For example, Thompson et al.[106] showed that cooking large pieces of beef under conditions of constantly rising temperature could lead to a rise in the heat resistance of *S. typhimurium* from a $D_{50°C}$-value of about 30 minutes to a value of about 80 minutes during the cooking process. Mackey and Derrick[61] showed that the heat resistance of *S. typhimurium* at 50°–59°C could be increased several hundred-fold by prior incubation at 48°C for 30 minutes. When heated at steadily rising temperature, the greatest increase in resistance resulted when the temperature rose most slowly.[62]

3.2.3 Moist-Heat versus Dry-Heat Microbial Destruction

It has long been known that spores are killed quickly and at comparatively low temperatures in a steam autoclave compared with a dry-heat oven. Death rate is a function of water activity (a_w) or equilibrium relative humidity (ERH).[68] "Moist heat" is a condition where the a_w is close to 1.0, and all conditions below this are "dry heat," but heat resistance varies with a_w such that it is maximal at values near to 0.3 (30% ERH; Figure 3-5).

3.3 DETERMINATION OF RESISTANCE TO MOIST HEAT

It is not possible to instantly heat a sample of microorganisms, hold them at a test temperature, then instantly cool them prior to enumerating survivors. There will always be a heating and a cooling lag, depending on the volume of the substrate and the physical nature of the carrier. When short heating times are used, eg, less than about 3 minutes, the substrate volume must be very small, and the vehicle in which the heating is carried out designed in such a way that the sample will reach the test temperature in a fraction of a minute. The microorganism substrate carriers listed in Table 3-1 and the heating systems listed in Table 3-2 cover a range of conditions and types of heating medium.

3.3.1 Methods

A variety of laboratory methods have been developed for both *successive sampling* and for *multiple replicate unit sampling*. In general, successive sampling methods are used in survivor curve studies, while multiple replicate unit sampling methods are used for both survivor curve and "endpoint-quantal" studies (in which heated samples show growth or no growth). In successive sampling, the test suspension is in one single container that is sampled at intervals, so that the survivor curve reflects changes in the microbial population in one unit. In multiple replicate unit sampling, identical replicate test units are each sampled only once. Usually there are three to five replicates, enumerated in duplicate, for each of five or more heating times in a survivor curve experiment. In endpoint-quantal studies, 10 to 20 replicates at six or more heating times should be used when the results are to be scored on a growth/no growth basis.

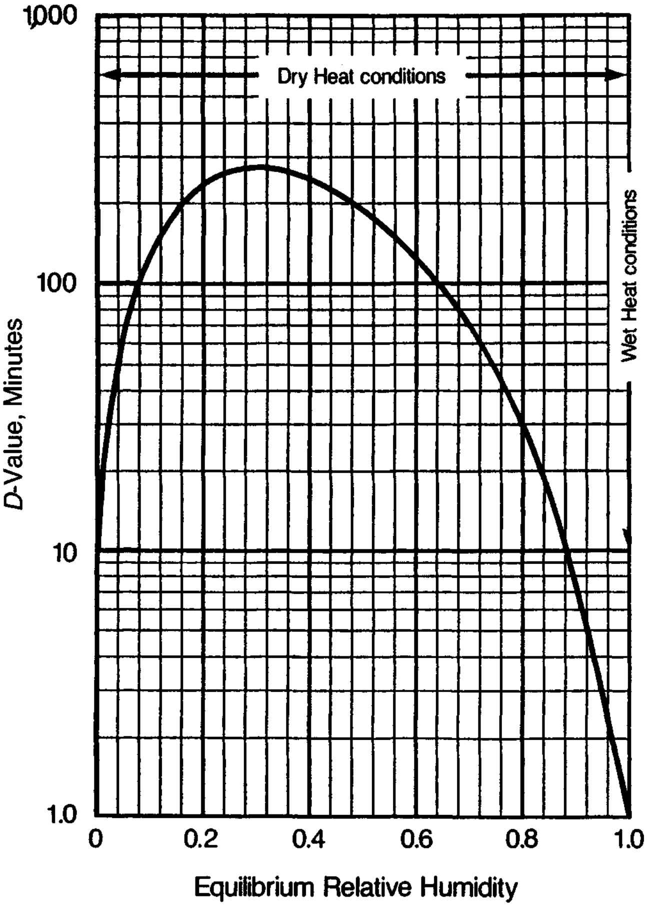

Figure 3-5 General Dependence of D_T-Values on Water Activity (a_w; scale 0 to 1.0) or Equilibrium Relative Humidity (ERH; scale 0 to 100%). *Source:* Copyright © 1995, I.J. Pflug.

Successive Sampling Systems

The primary apparatus is the flask or bottle containing the test substrate, which is submerged in a large water or oil bath with sensitive temperature control, and equilibrated at the required temperature. A small volume of suspension is inoculated into a large volume of heated diluent and samples

Table 3-1 Inoculum Substrate Containers Used in Multiple Replicate Unit Methods To Determine the Heat Resistance of Microorganisms

Container	*Substrate + Inoculum Volume (ml)*	*Heating Apparatus Required*	*Suitability of Method for Substrate Incubation or Culture*	*Heating Lag Correction; z = 10°C or 18°F (minutes)*
Glass tube, sealed	2	Waterbath to 90°C; above 90°C, oil bath, miniature autoclave or retort	Subculture or substrate incubation	0.9 to 1.2
Glass tube, 18 × 150 mm, screw capped	2–5	Waterbath to 90°C; above 90°C, oil bath, miniature autoclave or retort	Subculture or substrate incubation	2.0 minutes for 5 ml water in 18 × 150 mm test tubes (unless preheated)
Metal tube A1, 150 × 3 mm	1	Waterbath to 90°C; above 90°C, oil bath, miniature autoclave or retort	Subculture only	0.2 for 1 ml water
Capillary tube, glass	0,01	Special oil bath, cooling bath and transfer mechanism	Subculture only	Negligible
TDT can*	13 to 16	Waterbath to 90°C; above 90°C, oil bath, miniature autoclave or retort	Substrate incubation	0.6 to 2.0 in steam
Cup	0.01 to 0.02	Miniature autoclave or retort	Subculture only	Negligible
Cup-can system	0.01 to 0.02	Waterbath to 90°C; above 90°C, oil bath, miniature autoclave or retort	Subculture only	Negligible
Cup-resistometer	0.01 to 0.02	Thermoresistometer	Subculture only	Negligible

are removed periodically. Unless these systems are completely closed and completely immersed in the heating bath, they suffer from the problem of surface cooling, which can lead to artifactual "tails" on survivor curves, particularly when the tests cover many log cycles of destruction.

Multiple Replicate Unit Test Systems

Sealed glass tubes. Suspensions of bacteria are filled into 7- to 9-mm OD Pyrex glass ampules; the filled units are heat sealed, then heated in a water bath, oil bath, or biological indicator-evaluation resistometer (BIER) system (described below). After the tubes have been heated they are scored, broken, and the contents removed. This was the procedure used by Bigelow and Esty[14] and is still widely used.[60]

Screw-capped tubes. Pyrex glass test tubes with screw-capped closures can be used in the same manner as heat-sealed glass tubes. They are reusable and eliminate the heat sealing and breaking steps; however, their heating lag corrections are large. A screw-capped tube technique is available that makes possible accurate heating at temperatures above 100°C.[55] Tubes containing the test liquid are preheated, submerged in an oil bath, then a small sample of spores or vegetative bacteria is injected into each tube, while still submerged, through a neoprene septum using a Hamilton syringe. At the end of heating, the tubes are cooled in an ice water bath. This method essentially eliminates heating lag corrections; however, there is a small test temperature drop when the spores or bacteria are added. The method can be used for both plate count and endpoint-quantal analyses.

Capillary tube method. This method[101,117] is similar to the sealed-glass tube method, except that the diameter of the tube is reduced to a capillary so both heating and cooling take place rapidly. Tubes are of the order of 1.7 to 1.9 mm OD with a 1.0 to 1.3 ID; volume is about 0.05 ml.

Metal tube method. Metal tubes,[63,70] with diameters between those of capillary tubes and 7- or 15-mm OD glass tubes, eg, 150 mm long, 3 mm in diameter, and volume 1.0 ml, are very useful test units when heating times need to be short. They have a

Table 3-2 Heating Equipment Used in Multiple Replicate Unit Testing Systems

Heating Equipment	*Units That Can Be Accommodated*	*Capacity of Units*	*Complexity of Operation*	*Utilities Required*	*Relative Cost*
Waterbath	Glass tubes, sealed, cotton plugged, screw capped; metal tubes; TDT cans*	Limited by physical size of apparatus	Simple	Low pressure steam or electricity	Low
Oil bath	Glass tubes, sealed; metal tubes; TDT cans	Limited by physical size of apparatus	Simple	Electricity	Low
Miniature steam autoclave or retort	Glass tubes, sealed, screw capped; metal tubes; TDT cans; cups, cups in cans	Limited by size of apparatus	Simple	80 psig steam	Moderate
Thermoresistometer	Cups	5 or 6 cups, depending on design	Complex	80 psig steam or electricity	Expensive

*Thermal death time cans.

small lag correction factor (about 0.2 minutes) because the metal surrounding the column of substrate has a high heat conductivity and the column is small in diameter. The ends of the tube are internally threaded, and each end is closed with a plastic screw cap and O-ring. Metal tubes can be heated in an oil bath or a BIER vessel, and they are reusable.

Can method. Metal cans 2.5 inches (63.3 mm) in diameter by 0.375 inches (9.52 mm) high (in sanitary can terminology 208 × 006) were designed by the American Can Company[107] for use in thermal destruction studies of bacteria where the test product may be solid or contain large particles in a liquid.

Submerged coil method. In this procedure, a suspension of microorganisms is injected rapidly into a preheated, small-bore metal coil immersed and pre-equilibrated in a heated water bath so that heat-up time is short. An automatic syringe displaces aliquots to expel samples at predetermined intervals. The advantages of the method include the possibility of very rapid sampling rates.[33]

When heating times are very short, gathering accurate heat destruction data is problematic because of heating and cooling lags. An older method of treating heating and cooling lags is to calculate correction factors.[77] Another method is to calculate the heat effect during the thermal destruction experiment by accurately measuring the temperatures of the test sample during the heating up, holding, and cooling parts of the test, and summing the data, using the General Method Calculation Procedure.[54,77] For example, in a study of the effect of heat on spores of nonproteolytic *C. botulinum*, temperatures were recorded at 5- and 6-second intervals on a data logger and the information was analyzed on a microcomputer.[71] For each measurement temperature (T_m) the lethal rate (L) with reference to the target temperature (T_t) was calculated using the formula $L = {}_{10}[(T_m - T_t)/z]$ and a z-value of 8.0°C. The lethality of the treatment as equivalent time (minutes) at the target temperature was calculated from these data.

In determination of lags during heating and cooling, ie, the time required for the sample to reach the specified temperature, and in the determination of correction factors, it is essential that equipment for temperature measurement should be calibrated against a certified reference before and after each test.

3.3.2 Heating Systems

All heating systems must have sensitive temperature control and accurate temperature measurement (Table 3-2).

Waterbath. A waterbath is the ideal heating unit for temperatures below about 96°C. Baths should be equipped with efficient stirring devices to ensure uniform temperature and should be validated before use. The point-to-point or time cycle in temperature should be no more than 0.2°C. The lag correction factors for all types of product container units must be determined in the waterbath under the same conditions as will be used in the test. Units heated in a waterbath must be totally submerged during the time in the bath (see below).

Oil bath. An oil bath can be used for thermal inactivation testing over the range 95°–120°C. The upper limit is usually imposed by the heating lag in relation to the rate of inactivation of the spores, the lower limit by the more convenient use of a waterbath. The same type of temperature validation should be used as for a waterbath. The bath must be equipped with an effective stirrer. The heating lag correction is much larger when heating in oil than when heating in water or steam. Failure to totally submerge a test unit will usually result in a few survivors in the cooler out-of-bath part of the unit at time when the organisms in the bottom of the unit have all been killed, and therefore lead to tailing of log survivor curves.

BIER/steam vessel (miniature retort). The Association for the Advancement of Medical Instrumentation (AAMI) in Arlington, Virginia, developed standards for laboratory equipment to evaluate biological indicators used to validate and monitor sterilization processes. The equipment to mimic a steam autoclave was designated as a BIER/steam vessel (biological indicator-evaluation resistometer for saturated steam). This terminology is now often used to mean a small (miniature) saturated steam autoclave or retort where the test temperature can be accurately controlled. The BIER vessel[84,96] is a small pressure vessel that is capable of a rapid come-up-to-temperature. The retorts are usually connected, using large piping and quick action–type valves, to a large reservoir tank where the steam temperature is accurately controlled. The sequence of actions and temperature cycling in modern thermoresistometers has been further improved by computer control.[21]

3.4 SELECTING THE F_T-VALUE FOR LOW-ACID CANNED FOODS

The F_T-value is the sum of the lethal effects of a heat process expressed as minutes at a specified reference temperature, T (see definitions in Appendix 3-A), and forms the basis for establishing thermal processes.

When examining the available alternatives for systems to aid the establishment of microbial control values for low-acid thermally processed foods, the straight-line semi-logarithmic microbial destruction model is the accepted empirical approach to having an engineering model to use in the design and validation of microbial control processes. The equation that describes this model for moist-heat microbial destruction is

$$\log N_U = \log N_0 - U/D_T$$

where N_U = the number of microorganisms suviving a heat process of U minutes at temperature T; D_T is the decimal reduction time of the particular microorganism at temperature T, and N_0 is the initial microbial load.

Here is the equation rearranged in terms of U:

$$U = D_T (\log N_0 - \log N_U)$$

While it is appreciated that the semi-logarithmic model does not accurately fit all microbial destruction data,[80] to date we know of no other model that fits all experimental data. In practice, the appropriate parameters, N_0 and D_T, of the model can be adjusted so the model represents a worst-case condition (the greatest degree of safety) based on actual microbial destruction data. Fortunately, the endpoint term, N_U (numbers of survivors at the end of the process), of the semi-logarithmic model seems to have been designed to fit with the idea that the endpoint of a microbial control process should be a numerical specification. If the endpoint specification for spoilage by a mesophilic spore former is one nonsterile unit in 10^6 units, then on a unit basis, one out of 10^6 units is nonsterile, and the N_U-value will be $1/10^6$ or 10^{-6}. Therefore, the semilogarithmic model not only acts to relate the microbial destruction variables, but also aids in realistically describing the endpoint of the process, provided we can make some reasonable estimate of N_0 in practical situations.

There are then a few basic ideas in the approach to microbial control processes: (1) the experimental observations that one-celled organisms die in a near-geometric progression; (2) the selection of the F_T-value for canned foods should be approached in the order listed in Exhibit 3-1; and (3) process failure will usually be due to two or more independant changes in the process that act together. There are probably few one-cause failures.

3.4.1 Limitations in the Processing of Low-Acid Canned Foods

A canned food product may spoil either from growth of microorganisms surviving the heat process or from organisms that contaminate the product after it has received the heat process. With the

Exhibit 3-1 Priority Order for Design of Low-Acid Canned Food Process F_T-Value

1. ***Safe from a public health standpoint***[*]
   Probability of a viable *C. botulinum* spore surviving in a container of food should be of the order of 10^{-9} (PNSU-PH = 10^{-9}).[†]
2. ***Preserved against spoilage by nonpathogenic microorganisms***
   The term "commercial sterilization" has been widely used to cover this aspect of the microbial control process.
3. ***Preserved against mesophilic spore-forming organisms***
   Probability of a mesophilic organism surviving the microbial control process should be of the order of 10^{-6} (PNSU-M = 10^{-6}).[‡]
4. ***Preserved against thermophilic spore-forming organisms***
   Probability of a thermophilic organism surviving the microbial control process for a can of food to be stored below the growth range of thermophilic organisms (30°C) should be equal to or less than 10^{-2} (PNSU-T = 10^{-2}).[§] If the canned food is stored at elevated temperatures, the probability of survival should be 10^{-6} (PNSU-T = 10^{-6}).

[*] A minimum heat treatment sufficient to give a 12 decimal reduction in numbers of spores of *C. botulinum* is specified. If a maximum number of 1,000 spores of *C. botulinum* per container is assumed, this would give a probability of survival of approximately one spore in 10^9 containers.

[†] PNSU-PH: Probability of nonsterile unit-public health concern.

[‡] PNSU-M: Probability of nonsterile unit-mesophilic spoilage concern.

[§] PNSU-T: Probability of nonsterile unit-thermophilic spoilage concern.

production of millions of containers of a food product per annum throughout the world, some will not be hermetically sealed, and it is possible for microorganisms to enter nonhermetic containers. However, the probability of occurrence is not the same for both failure modes, as discussed by Pflug and Odlaug.[82] Post–heat processing contamination is a problem that must be addressed and controlled quite separately from the destruction of contaminating microorganisms by the heat process.[90] The increased use in the 1990s of two-piece metal cans and three-piece metal cans with a welded side seam has greatly reduced post-processing contamination.

In the determination of the F_T-value for heat process design purposes, microorganisms are assumed to be at the slowest heating zone of the container of product, or to be uniformly distributed throughout the product. Of course, it is accepted that this is not necessarily so, and the implications of microbial location on the design of the heat process were discussed in detail by Ball and Olson[9] and Stumbo.[103]

3.4.2 Determination of the Heat Process F_T-Value

In the heat processing of low-acid canned foods, the first consideration is that the product should not be a public health hazard.[112] Spoilage that represents an economic loss is considered to be secondary to public health considerations. Economic loss may occur from spoilage either by mesophilic or by thermophilic spore-forming organisms (Exhibit 3-1).[113]

Selection of the heat process F_T-value ideally proceeds in a two-step fashion: (1) the F_T-value necessary for the product to be safe from a public health standpoint is calculated; (2) the F_T for preservation against spoilage by nonpathogenic mesophilic spore-forming organisms, and the F_T for preservation against nonpathogenic thermophilic spore-forming organisms are calculated. The larger value is then used to establish the retort or autoclave process. This approach is illustrated in Table 3-3 with the probability values used by Pflug.[77] Two generally accepted approaches to the selection of F_T-values are then:

1. ***The use of generally accepted empirical F_T-values.*** The experience of more than half a century of successful preservation of low-acid canned foods is available to the microbial control process design technologist in the form of empirical F_0 values (the F-values when T is 121.1°C (250°F) and the z-value is 10°C (18°F, see below). These have been proven over time, and hence have broad, safe applications. Procedures have been developed to take advantage of any antimicrobial-generating attributes of the food product.
2. ***The design of the microbial control process specifically for the product container unit.*** In this method, one uses an accepted model, where the D_T-value and, on the basis of available experimental determinations, an estimate is made of the maximum number of the critical microorganisms in or on a product. This allows for examination of the design of the preservation process in great detail, resulting in the development of a better understanding of the factors that impinge on the final F_T-value. The input values in this design will come primarily

Table 3-3 F_0-Values for Low-Acid Canned Foods

Hazard	*Endpoint Probability**	F_0 *(minutes)*†
Public health	10^{-9}	3‡
Preservation		
—Mesophilic spores	10^{-6}	3–7§
—Thermophilic spores		
Warehouse and distribution temperature below 30°C	10^{-2}	3–7§
Warehouse and distribution temperature above 30°C	10^{-6}	15–21§

*Endpoint probability of survival of organisms in a unit. This assumes a probable maximum initial number of 10^3, as well as the probability of survival (eg, 10^{-12} for spores of proteolytic strains of *C. botulinum*).

†F_0 is the equivalent minutes at 250.0°F (121.1°C) calculated using a *z*-value of 18.0°F (10.0°C).

‡Based on the laboratory data of Esty and Meyer.[42]

§Based on industry experience (empirical data).

from experience, but should be adjusted for local conditions.

Calculating F_T-Values Using the Straight-Line Semi-Logarithmic Model

A case has been made previously for using the straight-line semi-logarithmic model as the heat process (F_T-value) design model. In the following development, the model is used on a container basis. In using the model,

$$F_T = D_T(\log N_0 - \log N_F)$$

F_T = heat process value, equivalent minutes at temperature T, z-value taken as 10°C (18°F)

D_T = decimal reduction time, time in minutes for a 90% reduction in the critical resistant microbial population

N_0 = initial number of critical resistant microorganisms per unit

N_F = the endpoint of the preservation process, the number of surviving microorganisms per unit

The endpoint value (N_F) is a consumer protection value, and is hence not product specific. The values N_0 and D_T are product specific.

F_0-Values for Low-Acid Canned Foods

Table 3-3 shows practical F_0-values for low-acid canned foods. These are the commonly accepted best estimates of the net F_0 required for microbial control. Data to support the "empirical F_0-values" in Table 3-3 are from different sources. This is possible because of the nature of industry experience with low-acid canned foods, and the F_0-values necessary for preservation against spoilage by nonpathogenic mesophilic and thermophilic spore formers. We do not have an empirical database showing survival of *C. botulinum* spores in cans. Consequently, we must use laboratory data as the basis for the public health, microbial control value against *C. botulinum.*

The empirical F_0-values of 3 to 7 minutes given in Table 3-3 for mesophilic spores are validated by industry practice of using a 5-log reduction of *Clostridium sporogenes* PA3679 spores having a $D_{121.1°C}$-value of 1.0 to 1.5 minutes as an adequate design. We estimate the practical $D_{121.1°C}$-value for resistant mesophilic spores in foods to be about 0.5 to 0.8 minutes, calculated using the straight-line semi-logarithmic model with an N_0 of 10^1 to 10^4 per unit and an endpoint value PNSU of 10^{-6}. The apparent resistance of the resistant mesophilic spores in the product is therefore approximately half of the maximum resistance value.

Safety from a Public Health Standpoint

The accepted approach to *C. botulinum* control is to use the F_0-value of Esty and Meyer[42] as corrected for heating and cooling stages by Townsend.[107] When this number (2.45 minutes) is rounded up, it becomes the F_0 of the 3.0 minutes *C. botulinum* process shown in Table 3-3.

The number of *C. botulinum* spores per container will vary with the food. For most low-acid foods, the initial number per container may be of the order of 10. For mushrooms, the N_0 may be as high as 10,000. For some meat products, the N_0 may only be one or fewer spores in 100 containers (<0.01 per container). For packaging materials and also for preformed packages used in aseptic packaging systems, there may be only one *C. botulinum* spore in or on the material to produce 10^5 packages; that is, 10^{-5} organisms per package.

Regarding the F_0-value necessary to ensure safety, Esty and Meyer[42] used approximately 10^{11} of the most resistant *C. botulinum* spores that they could grow per unit tested, and used as their endpoint no growth in about 10 replicates, which was a survival level of no more than 10^{-1}, so the log reduction for their experiments was about 12. The F_T-value developed by Esty and Meyer therefore will reduce a practical upper level of 10^3 *C. botulinum* spores per container to an endpoint probability of 10^{-9}. Today, more than 75 years after publication, these data are still quoted as the basis for selecting the minimum

F_0-value for preserving low-acid foods against botulism. The work of Esty and Meyer[42] is still one of the few published papers that provides data for validating an 11- or 12-log destruction of *C. botulinum* spores.[76]

Of course, the $D_{121.1°C}$ of 0.2 minutes does not necessarily represent the resistance of *C. botulinum* spores in food products, but tends to be the *maximum* value that could be produced in the laboratory. The *C. botulinum* spores that contaminate food raw materials are formed in nature. Because it is known that the growth medium affects spore resistance, it is probable that naturally occurring spores have different resistances from those determined in the laboratory studies. In this sense, the figures used so successfully for many years are probably conservative, and considerably "fail-safe"; on the other hand, the constituents of some foods are known to protect spores from heat inactivation.

In relation to the safety of meat products, extensive efforts have been made to ensure that meat does not contain the prions that are thought to cause bovine spongiform encephalopathy (BSE) and "new variant" Creutzfeldt-Jakob Disease (v-CJD; Chapter 57). The limited data available regarding the heat resistance of these prions indicate a heat resistance similar to that of the agent of scrapie,[105] which showed nonexponential inactivation kinetics.[22] Casolari[28] used these and other data to conclude that current thermal processes applied to foods would deliver little inactivation of these prions.

3.4.3 Preservation against Spoilage by Nonpathogenic Thermophilic Spores

The ambient temperature conditions of warehouses and distribution systems in some parts of the world are such that thermally processed foods that may be perfectly stable in cooler climates may run the risk of spoilage by thermophilic spore formers. Since many of these have heat resistances well above those of mesophilic spore formers and *C. botulinum*, especially severe heat processes may be necessary for their control. Thermophilic spore formers that spoil low-acid canned foods are often divided into three groups: (1) those that produce flat-sour spoilage (eg, *Bacillus stearothermophilus* and *B. coagulans*); (2) those that produce gas, but not hydrogen sulfide (eg, the thermophilic anaerobe *C. thermosaccharolyticum*; and (3) the thermophilic anaerobes that produce hydrogen sulfide spoilage (eg, *Desulfotomaculum nigrificans*, formerly *C. nigrificans*).

B. stearothermophilus and *B. coagulans* are the chief flat-sour thermophiles found in canned foods.[10,52,116] While both cause flat-sour spoilage, they have different characteristics. *B. coagulans* is a problem particularly in canned foods exposed to temperatures in the range from 40° to about 60°C and at pH values of 4.3 to 4.8. The $D_{121.1°C}$-values for laboratory-grown spores vary from about 0.2 to 1.0 minute depending on the strain and substrate and on the medium in which the spores were grown, heated, and recovered. *B. coagulans* is not a major flat-sour spoilage organism of low-acid canned foods, and its heat resistance is not much greater than that of the mesophilic spore formers discussed previously.

B. stearothermophilus is the primary cause of thermophilic flat-sour spoilage in low-acid canned foods because it will grow in the pH range from 5.4 to above 7, and has a $D_{121.1°C}$-value that is 5 to 10 times that of the resistant, mesophilic spore-forming organisms. *B. stearothermophilus*–type organisms sometimes may grow at temperatures as low as 37°C, but never below 30°C.[10,116]

C. thermosaccharolyticum is a very heat-resistant saccharolytic, thermophilic anaerobe that produces gas, and hence swelled-can spoilage. The optimum growth temperature is about 55°C; only rarely has growth been reported at temperatures as low as 30°C. Strains of this bacterium cause significant spoilage, especially in the pH range from 4.5 to 5. They are very heat resistant; *D*-values for spores at 121.1°C were reported as 3 to 4 minutes[103] and for one strain, more than 50 minutes.[119] It is usually not possible to produce an acceptable canned food product if the heat process must be designed to kill large numbers of *C. thermosaccharolyticum* spores. Canners try, therefore, to test batches of ingredients for this bacterium and to select for use batches with the minimum numbers of this organism.

Organisms of the group *Desulfotomaculum*, heat-resistant thermophilic anaerobes that produce hydrogen sulfide, are responsible for the so-called "sulfur-stinker" spoilage of canned foods. These organisms are only feebly saccharolytic; cans with spoiled product usually remain flat, since the hydrogen sulfide is soluble in the product. The product becomes black as a result of the interaction between the sulfur compounds and the iron in the containers. *D. nigrificans* is one of the most heat-resistant thermophilic organisms. The temperature range for growth is usually 45°–70°C, with an optimum at about 55°C; the bacterium can be adapted to grow slowly at 30°–37°C. Using a plate count survivor method, $D_{121.1^\circ C}$-values for spores of strain ATCC 7946 of 3.2 to 4.0 minutes in water and phosphate buffers, and 5.6 to 7.6 minutes in various broths have been reported.[39] When fraction-negative tests were used, a $D_{121.1^\circ C}$-value of 25.8 minutes was obtained for isolate ATCC 7946 and 54.4 minutes for isolate RGI.

In spite of these enormous resistance values, spoilage of foods by *D. nigrificans* tends to be rare. This may be due in part to the fact that because of the severe heat processes required, it may not be possible to produce a canned food of acceptable quality when a product contains large numbers of *D. nigrificans* spores; hence, only raw materials that have very low N_0 levels of these organisms are used.

If temperatures are expected to rise above 30°C during the expected distribution and/or shelf life of a canned food product, raw material quality and processing should be designed so that the probability of thermophilic spoilage should not exceed 10^{-6} for all product storage and handling conditions.

3.5 HEAT DELIVERY

There is a very wide range of methods available for the delivery of heat to foods. Some of them, eg, domestic cooking, are important from the standpoint of public health, but are not under strict control. On the other hand, the various methods of commercial processes for delivering heat to foods are tightly controlled.

3.5.1 Domestic and Commercial Cooking

One of the most important applications of heat is during food preparation to ensure the elimination of microorganisms including pathogens such as *Listeria monocytogenes*, *Salmonella* species, *Campylobacter* species, and pathogenic strains of *Escherichia coli*. The food cooking process is a most important step in making food microbiologically safe. When, in the cooking process, the slowest heating zone of a product is at or above 180°F (82.2°C) as is the case for most vegetable products, vegetative microorganisms and viral and fungal pathogens will be killed. Most vegetables are cooked by boiling. The end-of-cooking temperature for most vegetables is about 180°F, and starchy foods such as rice and potatoes are usually cooked to a temperature of 190°F (87.8°C) and above.

For chicken, pork, and game meat, the general recommendation is to cook to a temperature that will render the color of blood gray or brown, corresponding to a cooking temperature above about 165°F (74°C). If there are cooking processes and products that have special food safety aspects, these are with beef and lamb, where these products are often eaten in a rare or medium-done state. The USDA requirement for roast beef gives an indication of the microbial control capacity of the cooking operation. For salmonellae, they recommend a reduction in the initial load of 1×10^7 to one organism per gram of beef. (For ground beef, a suggested salmonella reduction is 5 log cycles.) A process of 121 minutes at 130°F (54.4°C), 12 minutes at 140°C (60.0°C), 1.2 minutes at 150°F (65.6°C), or 0.12 minutes at 160°F (71.1°C) is recommended for control.[109,111] These times and temperatures can be related to the American Meat Institute specifications for "doneness": 130°F produces very rare beef, 150°F produces medium beef, and 160°F produces well-done beef.

In baking, products are heated until the interior is at approximately 212°C (100°C), when the crust will be at a temperature slightly above the boiling point of water and steam will have been generated in the center of the product.

Simmering will result in a product temperature very close to the boiling point of water. The interior of products will generally reach at least 194°F (90°C). Specifications for food service and/or catering are to either keep food hot (above 140°F/60°C, except for beef: 130°F/54.4°C), or to chill it in less than 15 hours from 130°F (54.4°C) to 45°F (7.2°C) so that any surviving spores, especially of *Clostridium perfringens*, will not germinate and multiply.

In broiling and grilling, the core temperature will usually be of the order of 150°F (65.6°C) to 190°F (87.8°C), with the surfaces receiving radiant energy being at a higher temperature.

During frying, fat is the medium carrying heat to the product. For shallow pan- or deep fat-frying, the core temperature at the end of the frying period is commonly between 150°F (65.6°C) and 190°F (90°C). Similar temperatures will be reached during griddle cooking, which involves heating food on a hot metal surface without added fat.

In microwave cooking, heat is delivered predominantly via the excitation of water molecules in foods. The inactivation of microorganisms is determined by the temperature reached, just as with any other form of cooking.

3.5.2 Thermal Processing for Commercial Sterility

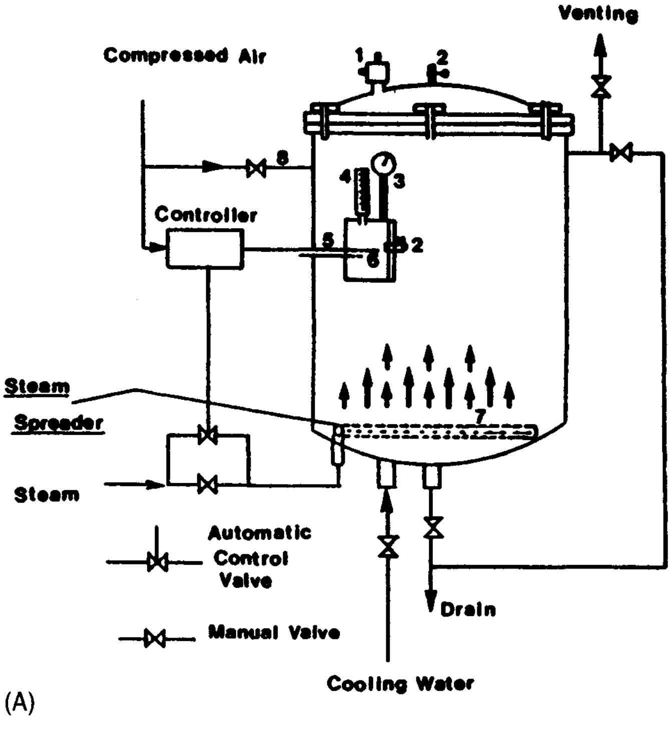
Still Retorts

The still (nonagitating, noncontinuous) retort, or autoclave, has been in use for more than 100 years as a device for processing low-acid foods above the boil-

Next Page

ing temperature of water. In many canning operations, the still retort has been largely replaced by continuous agitating retorts.[54,90] However, for the sterilization of conduction heating food products, for processing glass packed products, and for small companies that cannot justify the cost of an agitating retort system, the still retort remains the primary piece of heat processing equipment. Still retorts may be of a horizontal design, with the door at one end, or vertical, with the door at the top (Figure 3-6). Processing food in a still retort is a batch operation, however, the Malo system is unique in that the retort is filled and unloaded automatically. It is a crateless system where the cans are in a scrambled condition and can be handled as a fluid. However from the processing standpoint, it is a still retort.

General considerations that apply to the processing of containers in still retorts include the following: (1) In thermal process design, as part of the validation testing program, the slowest heating containers in a retort are identified and the process design is based on having an adequate process for these containers. (2) Heating rate data from heat penetration tests carried out in laboratory retorts and simulators can be used appropriately in the design of processes for commercial equipment. This is true in general but not universally; consequently, it is the responsibility of the sterilization technologist to determine the applicability of laboratory results and/or simulator results to the commercial equipment. (3) In general, the more complex the process, the more important it is that the test equipment be validated to ensure that the results from the test equipment are valid in the commercial equipment.



Heating media do not all perform in the same way, and can be considered in two classes: (1) 100% saturated steam and (2) water (with steam-air overpressure), water-spray (steam-air atmosphere), and steam-air mixtures. In a properly vented 100% steam retort, we have a saturated vapor heating medium in which the temperature is a function of pressure and, for practical purposes, the temperature at all container surfaces in the retort will be at the saturation temperature. All of the second class group of media require some type of mechanical mixing to keep the heating medium temperature approximately constant throughout the retort. In water and water-spray systems, pumps are used and in steam-air systems, large fans or blowers are used to circulate the heating medium.

Still retorts may be operated manually with very simple instrumentation or automatically with time/

(**A**) A vertical batch retort: 1, safety valve; 2, petcocks to maintain a steam bleed during processing; 3, pressure gauge; 4, thermometer; 5, sensing element for controller; 6, thermo-box; 7, steam spreader; 8, air inlet for pressure cooling. (**B**) A horizontal retort: A, steam; B, water; C, drain, overflow; D, vents, bleeder; E, air; F, safety valves and pressure relief valves. *Source:* Reprinted from P.S. Richardson and J.D. Selman, Heat Preserving Equipment, in *Processing and Packaging of Heat Preserved Foods,* J.A.G. Rees and J. Bettison, eds., pp. 50–71, © 1991, Aspen Publishers, Inc.

temperature cycle controls. The expenditure that can be justified for instrumentation generally must be related to the complexity of the process. For example, steam cooking of small-sized metal containers is a rather simple operation and warrants only temperature control, whereas processing glass packed products under water with superimposed air pressure will require pressure, temperature, and time cycle control to achieve the same efficiency. When pressure controls are used, corrections must be made for altitude.

In the processing of medium-sized cans of foods in still retorts, where steam is used as the heating medium and the cans are cooled with water either in the retort or in a cooling canal, it may be necessary to pressure cool the cans so that their ends remain concave during cooling. Steam may be used to maintain the pressure if the cold water is introduced from the bottom of the retort under a layer of hot water. A better solution is to use compressed air. Products packed in glass containers must be processed under water with superimposed air pressure. Glass packed products are cooled in the retort under water until the temperature of the food product has been reduced to below 150°F (65.6°C). The remainder of the cooling may take place in a cooling canal. The temperature of canned foods should be below 100°F (37.8°C) when cans are placed in the warehouse.

Flexible packages containing low-acid food products must be restrained in a rack to control pouch thickness during the sterilization process. The racks must be designed so that there is space between pouches for the heat transfer medium. Over-pressure must be used during cooling to avoid pack rupture.

Agitating, Discontinuous, Pressure Processing Machines

In general, processing machines in this category have some type of basket into which the containers of product are loaded. During the heat process the basket rotates (Figure 3-7), agitating the contents of the containers in the basket, which increases the rate of heat transfer, shortens the process, and reduces the overcooking of product in contact with the container walls.

Early in the 20th century, Fort Wayne and Berlin Chapman sterilizers were developed and widely used for sterilizing evaporated milk. These retorts contained a removable, large, rectangular perforated basket into which the cans were stacked. The filled basket was moved into the pressure vessel. Driven by an externally located motor, the basket filled with containers revolved on its own axis during processing. The rate of basket rotation was of the order of 6 to 12 rpm. Starting in about 1950, for high-volume products, continuous agitating pressure sterilizers tended to replace the end-over-end batch machines. Continuous processing machines are economical in operation but tend to be large, expensive, and designed for one product in one container size. The intermittent axial rotation of the continuous spiral cooker is adequate for liquids such as milk, but is inadequate to process some of the newer more exotic products where there are particulates in thick sauces. End-over-end rotation offers more flexibility when it comes to difficult-to-heat items in glass containers, flexible packages such as the "retort pouch," and semi-rigid containers. In the 1960s, a new generation of rotating basket machines appeared to meet these needs. The heat transfer media are either pressurized water (Stock Rotomat, Klinge, Allpax, Hisaka) or an air-steam mixture (LaGarde, Steristar).

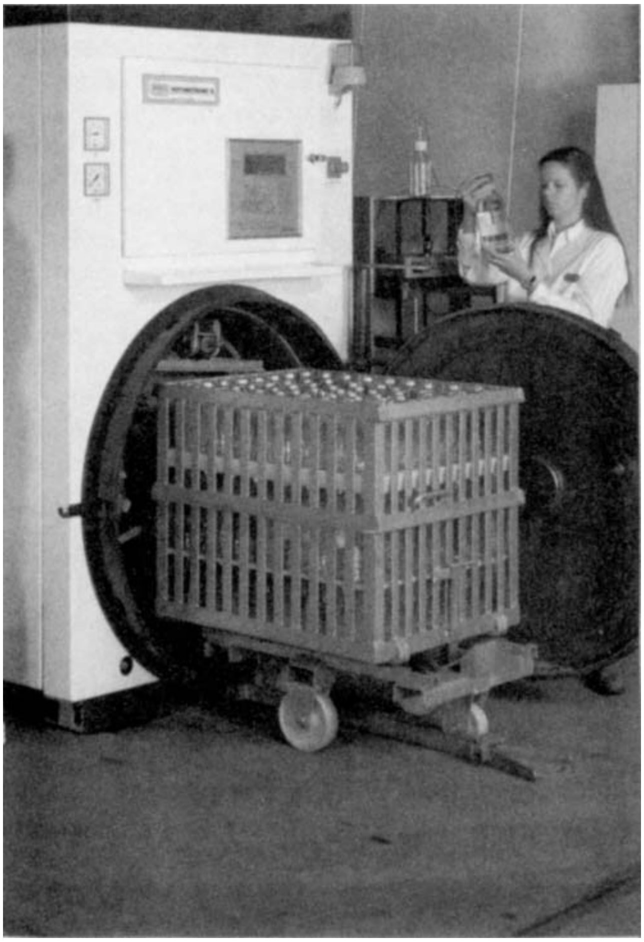


Figure 3-7 Rotating "End-Over-End" Sterilizer. Courtesy of STOCK America, Milwaukee, Wisconsin.

In general, today's rotary basket sterilizers have baskets or carts that are clamped into a rotating frame, and are part of a system where the individual baskets are at least semi-automatically loaded and unloaded. They are capable of handling a wide range of container geometries. The size and shape of the container, the position of the container in the container rack system, and basket rotational speed (20 to 30 rpm are used with viscous products) are selected so both the heat transfer and product quality needs are met. The slowest heating containers are at the axis of rotation. Those most distant from the axis of rotation receive the maximum agitation and consequently are likely to heat fastest. All present-day rotating basket machines utilize some positive means of ensuring uniformity of temperature of the heat transfer media through the crates. These processing machines are equipped with microprocessors and other types of computerized monitoring and control systems. Eisner[41] gives a full description of the operation and use of rotary basket sterilizers.

Continuous Hydrostatic Pressure Cooker–Cooler Systems

These systems are unique in being open so far as conveying is concerned, there are no valves or locks. A single chain conveyor with can-carrying flights is continuous throughout the entire system (Figure 3-8). Steam pressures of 10, 15, or 20 psi, necessary for sterilizing at 240°F (115.5°C), 250°F (121°C), or 260°F (126.7°C), are balanced by hydrostatic or water head pressures in the heating and cooling water legs. Net water heads of 23, 34.5, and 46 feet, respectively, are necessary to produce pressures of 10, 15, and 20 psi. The total tower height therefore varies with the temperature design; 40 feet for 240°F, 50.5 feet for 250°F, and 61 feet for 260°F. A minimum amount of floor space is required. A unit with a capacity of over 1,000 cans per minute occupies an area of only 13 × 26.5 feet.

Hydrostatic-type cookers are usually designed so that several can sizes can be used without major

equipment changes. In principle, the hydrostatic-type cooker is the least complicated continuous pressure cooker in use today. However, to make this simple principle into a practical piece of food processing equipment requires considerable mechanical equipment in the way of feeders, unloaders, conveyors, and controls. Corrosion is a constant problem. Efficiency is illustrated by a 3-in-1 hydrostatic sterilizing operation[93] that replaced 33 retorts and processed 35,000 cans per hour with savings of steam, water, labor, and floor space.

Continuous Agitating Pressure Sterilizers

The continuous agitating pressure sterilizing system (FMC) consists of separate units or components that are put together to form a sterilizing system (Figure 3-9). Components that are available are: preheater, pressure cooker, micro-cooler, pressure cooler, and atmospheric cooler. In general, the system is tailor made for a particular processing operation. In systems for sterilizing vacuum packed foods, it is necessary to have a preheater prior to the pressure cooker and a pressure cooler before the atmospheric cooler. The purpose of the preheating section, maintained at a moderate temperature and pressure, is to heat product to a temperature of 180°F (82.2°C) to 210°F (99°C), so that the internal pressure in the can is approximately one atmosphere (zero gauge pressure) when the cans enter the pressure cooking system.

The preheating, pressure cooking, and cooling sections all operate in the same manner. Each section consists of a cylindrical pressure tank inside of which is located a reel containing a helical track. The containers of food enter through a valve; they roll, slide, and are carried around until they reach the end of the unit where they are valved out. The containers receive a unique rotational pattern as they proceed through the units so that in a single revolution of the reel, the cans are carried around the top portion of the cooker, slide a short distance along the side, and then roll along the lower portion of the unit. The agitation received by the containers of food is sufficient to cause products that normally are considered to heat by conduction, such as cream-style corn, to heat almost as fast as normal convection heating products. Steam is used as the heating medium and cold water is used as the cooling medium. The units are equipped with automatic temperature controls in the heating section and water level controls in the cooling section, and conveyors are used to make a continuous processing system.

The advantages of the continuous agitating pressure sterilizing systems are that they reduce processing times and costs, and a uniform cook is obtained. High operating temperatures, 260°F (126.7°C) or 280°F (137.8°C), plus agitation substantially reduce the processing time for convection heating foods. Certain food products that are normally heated by conduction can be induced to heat by convection, resulting in a major saving in time and improvement in quality. Prior to 1950, continuous cookers were restricted primarily to milk, peas in brine, and tomato products. However, since 1950, with the development of a new type of cream-style corn, they have been widely adapted for the processing of this product as well as brine-packed corn, soups, and formulated infant foods.

Hydrolock System

The Hydrolock is the name given to a continuous agitating pressure sterilizing machine in which the containers move through the system in carriers on a chain similar to the handling system of a hydrostatic processing machine. The chain with the carriers makes several passes horizontally the long way of the cylindrical pressure chamber. The top section of the pressure chamber is filled with steam plus air. Cold water for cooling is in the bottom of the horizontal cylinder. The heating and cooling sections are separated by a baffle. Fans are used to circulate the heating medium when steam-air mixtures are used. The product carrier chains move in and out of the pressure chamber through a single rotary valve that is water sealed, hence the name Hydrolock. Containers may be continuously rotated by contact between the carriers and a belt directly below the carriers.

Hydrolock processing machines are used in Europe and Asia for commercial sterilization of fruits, vegetables, and milk products, and in North America for sterilizing pharmaceutical products. The Hydrolock machines can process products in both metal and plastic containers.

Flame Heating

Flame sterilization is a method of rapidly heating cans of food to effect sterilization by placing the cans in direct contact with a gas burner flame while they are rapidly rotated. The rotation induces convection heat transfer of the product in the container. The heat transfer rate from flame to can is very high because of the huge temperature difference even though the heat transfer coefficient is relatively low. Flame sterilization is recommended by the inventors for liquid food products and for particulate products packed in brine, syrup, or juice. The concept was developed by Cheftel in France.[13,32] Much work has been done on this process by Casimir in Australia[23–25] and Leonard in California.[56–58]

The chief attraction of the method is the rapid heating of the containers of product. The processing machines are continuous and have relatively low initial cost but relatively high energy consumption. The temperature of the gas flame varies between 2,000° and 2,500°F (1,090° and 1,370°C). The system operates at atmospheric pressure, therefore the can must withstand the internal pressure that is developed; a 3.2-inch (81-mm) can is probably the largest that can be processed satisfactorily. In general, the can end must be stronger (heavier plate) when flame sterilization is used than when the product is to be retort sterilized.

The most difficult problem of flame heating is that of obtaining uniform product temperature so that a constant *F*-value is delivered to the product in all the containers. Directing a flame onto a can and surrounding a can with hot gases is not as controlled a procedure as placing a can in a retort filled with steam. Therefore, there is a problem of underprocessing, eg, if a can misses the flame, the flame is not at the right intensity, or some other condition exists that results in inadequate flame contact time with the can.

The flame sterilizer is under a unique constraint. When product temperatures within the can exceed perhaps 280°F (138°C), the internal pressure will cause the can to fail with explosive violence. On the other hand, deflection of the flame for even a fraction of the short heating period will mean that very little heat is transferred to the container, and gross underprocessing will result. A system therefore has been developed whereby the temperature of each can passing through the system is monitored to ensure that all cans receive an adequate sterilization *F*-value. The limited control of the flame heating procedure will necessitate some such type of positive monitoring of all containers if this system is to be commercially acceptable for the processing of low-acid foods.[23–25]

3.5.3 Processing of Acid Foods

In commercial processing of foods in most countries, products with a pH of 4.6 or lower (US) or lower than 4.5 (UK) are deemed to be acid foods and can, in general, be made shelf stable by processing at temperatures below 212°F (100°C). Products such as canned acidified cucumbers and other vegetables, fruit juices, and tomato products are made shelf stable by a heat treatment in one of the following four types of equipment: waterbath heating systems, steam-air heating systems, water-spray systems, and continuous agitating atmospheric cookers.

Waterbath Pasteurizers

A waterbath is an ideal piece of equipment for the pasteurization of products such as pickles. Temperature control can be very good, the heating rate is comparable to that in water-spray or steam-air pasteurizers, and the equipment is simple to operate and relatively inexpensive. Many systems are being used, which vary according to the materials used for construction of the waterbath, the method of handling jars or other containers, and the procedure used in heating and cooling. Wooden tanks, vertical type three-crate retorts (with the lids removed) and fabricated steel tanks are all used. The methods of handling the jars or containers vary. In some cases, the jars are hand stacked into wooden tanks, the tanks are filled with water, and the water heated by the direct injection of steam. This is one of the original methods of making fresh cucumber pickles, though not used extensively in large operations. Retort baskets or crates for holding jars or cans of pickles and three-crate vertical retorts are still used in many maufacturing plants. In others, rectangular tanks with fabricated rectangular baskets are used. Where baskets or racks are used for holding the pickle jars, the procedure is to place the containers of pickles in water that has been preheated to 120°–140°F (49°–60°C). During the heating portion of the cycle, the water is maintained at 170°, 175°, or 180°F (77°, 79°, or 82°C). To cool the pickles, cold water can be added to displace the hot water. Otherwise, baskets of product are moved sequentially from preheating tanks to pasteurizing tanks, then into tempering tanks and into cooling tanks.

The waterbath system is, for all intents and purposes, a batch system, and has the disadvantage of high labor requirements. It is best adapted to small or specialty operations where the quantity of product does not warrant the installation of a continuous system.

Steam-Air Pasteurizers

The typical steam-air pasteurizer is a rectangular tunnel 7 feet wide, 2 feet high, and about 100 feet long and open at both ends. An endless-type stainless steel chain conveyor passes through the tunnel and conveys the product continuously through the unit. The pasteurizer is usually constructed in 10-feet long sections with canvas baffles between the sections to keep air currents from blowing the steam-air mixture out of the tunnel, and consists of a heating area, holding area, and cooling area. The heating sections are fitted with steam pipes containing small orifices; the steam pipes are usually located at the top of the pasteurizer. Cooling is carried out by water sprays. The cooling section is equally as critical as the heating section, and high cooling water temperatures can limit production rates. The jars of product, such as pickles, enter the pasteurizer and proceed through one section after another, where heat flows into the containers. They are held in a nonheating, noncooling section for a few minutes for tempering, then moved into the cooling section where they are cooled to warehousing temperature.

The advantage of the steam-air pasteurizer is that it is a continuous processing unit; corrosion in the heating section is reduced over water-spray–type pasteurizers through a reduction in the quantity of equipment that is used and that comes in contact with corrosive fluids. The disadvantages are principally those associated with temperature control of the pasteurizer.

Water-Spray Pasteurizers

The water-spray pasteurizer is very similar to the steam-air pasteurizer. The difference is that whereas the steam-air pasteurizer uses a gaseous steam-air atmosphere as a heating medium, the water-spray pasteurizer sprays heated water over the containers. The cooling section is the same for both types of systems. Pflug and Nicholas[81] found that water sprays were very effective in heating food containers; equal or faster heating resulted when a water spray was used than when a waterbath or 100% steam was used.

In general, water-spray pasteurizers are more expensive in initial cost than steam-air pasteurizers because of the need for pumps and water reservoir tanks and are thought to have higher maintenance costs. The heating rates in water-spray pasteurizers are equal to, or higher than, those in a steam-air pasteurizer, and a properly operated water-spray pasteurizer eliminates some of the temperature distribution problems that occur in steam-air tunnels.

Continuous Agitating Atmospheric Cookers

The continuous agitating atmospheric cooker is widely used for the processing of acid foods such as fruits, fruit juices, and tomato products. The can conveying section is identical to that of the continuous agitating pressure cooker (spiral cooker), in that the cans travel along a spiral track as they proceed through the unit. The difference is that the shell is not pressurized and, therefore, the heating medium is maintained at atmospheric pressure. These systems are used with both steam at atmospheric pressure, normally near 212°F (100°C), and as water cookers. A rather simple mechanism, instead of a pressurized valve, is used to feed cans into the unit. The atmospheric cooker is considerably less expensive than the continuous agitating pressure cooker because of the simpler feed mechanisms and the use of an open-topped tank.

3.5.4 Heat Treatment of Bulk Foods before Aseptic Packaging

It is much faster to heat and hold (until pasteurization or sterilization is accomplished) and cool a food product that can be pumped through a system, then to pack it aseptically, than to heat treat a product after it has been sealed in a container. The three major heating systems used are heat exchangers, steam injection, and ohmic heaters.

Heat Exchangers

Under a given set of conditions, the rate of heating of a product in a heat exchanger depends on the distance the heat has to flow (rate of heat flow varies inversely with the square of the thickness) and the degree of agitating or mixing. In general, *heat exchanger* is the name given to a device designed to allow heat to flow from one fluid to another as economically as possible. The distance the heat must flow is made small, and the rate of fluid flow of both the heating medium and the product are as high as economical pumping will permit because short heat flow distances and high velocities produce the highest heat transfer rates. The chief limiting factor is that the product must be of such a consistency that it can be pumped through the heat exchanger.

Common types of heat exchangers are (1) *tubular heat exchangers* in which round or flattened tubes are used and the product normally flows through the tubes, with the heating medium surrounding them; (2) *plate heat exchangers* in which a series of plates is built up with appropriate openings and gaskets so that the heating medium is on one side of each plate and the product is on the other. Plate heat exchangers have a great amount of surface in relation to their physical size and are now available in designs that permit heating to 250°F (121°C), using steam as the heating medium, and are of such construction that the food products can be used as either the heating or the cooling medium; (3) *scraped-surface heat exchangers* are large diameter, tubular heat exchangers in which there is a mechanical scraping device to help agitate the product and keep product next to the wall continuously scraped and mixed with the remainder of the product. Scraped surface heat exchangers have very large heat transfer coefficients.

Steam Injection

Direct injection heating units, such as the Vacreater or the Fitzpatrick Calefactor, have large heating capacities for their physical size. Assuming that the product is at 150°F (65.5°C), and the designed temperature is 250°F (121°C), then 1 pound of steam will heat approximately 10 pounds of product. However, 1 pound of water will be added to the product. The advantage of this system is obvious in that the heat energy is injected directly into the product, and there is merely an equilibrium to be reached, which is the new temperature. The weight of steam that is added, of course, condenses to water. However, this is normally removed in a flash tank where the heated product, after having been held long enough to achieve sterilization, is flashed to a low pressure that will bring it back to the original temperature through the evaporation of a quantity of water approximately equal to that added to heat the product. When using direct steam injection heating, the processor must take adequate precautions to guard against the addition of impurities contained in the steam. There are heat exchange units now available where purified, softened, hot tap water can be converted into steam from the central boiler as a heat source. In this way, the processor has direct control over the material added to the product.

Ohmic (Electrical Resistance) Heating

Ohmic is the name given to an electrical resistance heating food product machine. The basic principle is that an alternating current voltage is imposed, through a pair of electrodes, on an electrically conducting food product with the result that heat is produced in proportion to the voltage imposed and the resistance of the food product. Resistance heating is an old technology. What is new is the engineering development of a system that makes it practical to use the system to heat food. Systems have been developed for continuously heating pumpable products prior to aseptic packaging (Figure 3-10). The developers of the present systems indicate that it can be used to heat particles up to about 25 mm in diameter. An advantage of the process is that for particles of uniform electrical resistance, there will be uniform heating throughout the particle. Because the input to the processing system is electrical energy, the energy cost may be higher than for systems where fossil fuels are used as the energy sources. The advantage of the ohmic over the steam injection system is that particles will be heated uniformly throughout rather than requiring heat to flow from the outside of the particle to its center by conduction heat transfer, as is the case if the particles are being pumped through a heat exchanger.

The rate of heating is a function of the power put into the system. Heating is dependent on the electrical conductivities of the raw materials. This type of heating should be considered when it is necessary to increase the rate of heat penetration into particles in pumpable liquids, and also when it may be desirable to decrease the length of the heating period. There is no similar system for increasing the rate of heat flow out of a product after it has been heated, so cooling has to be carried out in conventional heat exchang-

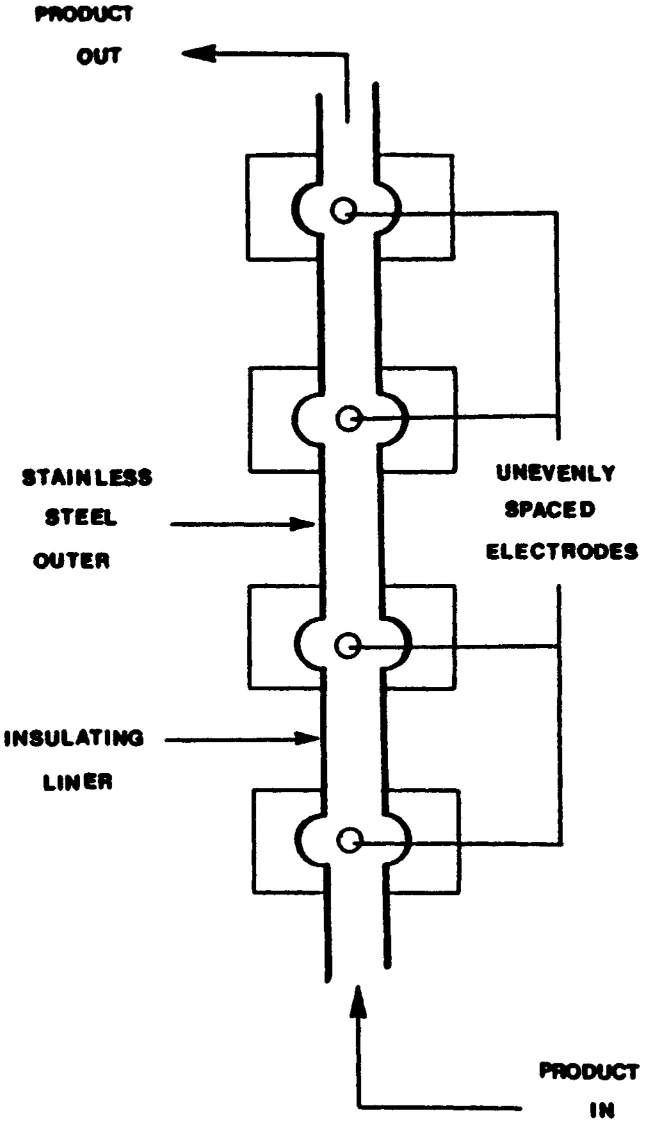

Figure 3-10 APV Ohmic Heater. *Source:* Reprinted from P.S. Richardson and J.D. Selman, Heat Preserving Equipment, in *Processing and Packaging of Heat Preserved Foods,* J.A.G. Rees and J. Bettison, eds., © 1991, Aspen Publishers, Inc.

ers. The role of ohmic heating in aseptic processing was summarized by Dignan et al.[38] and Fryer.[46]

Microwave Heating

Microwave cooking is heating by radio frequency excitation of water molecules in a food. There are no special killing effects from the radio frequencies used.[67] Kill is determined by the food temperature just as it is in other forms of cooking, though the overall effectiveness may be impaired by uneven heating. Microwave energy is used to heat some types of products on a continuous basis, where the product has been filled into a flexible package and is then heated in a microwave tunnel, sealed, and distributed as a chilled food with an extended shelf life.

In general, ohmic heating is most usefully applied to liquid systems whereas microwave heating is more applicable to solid foods. Both microwave and ohmic heating systems at the plant site use, as energy input, electricity, whereas heat exchanger systems, using steam or water or steam injection, can use fossil fuel energy sources, which may make the energy less expensive.

3.5.5 Aseptic Packaging

Aseptic packaging must be used if low-acid foods are sterilized in bulk. Puddings, juices, milk and milk products, vegetable soups, and purees are examples of the many products that are aseptically packaged.[90]

The Dole aseptic system, dating from about 1950, was probably the first major commercial aseptic system and is still in use. It was designed to use metal containers. From 1950 to 1980, there was continual progress in the development of aseptic packaging systems for bulk products, but little development for retail products. In the 1980s, there was a resurgence of interest in aseptic processing because of two major developments: (1) in the US, the Food and Drug Administration (FDA) approved the use of hydrogen peroxide for sterilization of aseptic packaging materials[4] and (2) form-fill-seal technology, using paperboard laminates to aseptically pack juices and other high-acid products was introduced.[89]

A large number of package types are now used in aseptic systems. These include metal cans, composite cans, thermoformed cups, tubs and trays, plastic laminated pouches, paper-plastic foil cartons, blow-molded bottles of many different shapes and sizes, plastic bags inside cardboard boxes, and very large stainless steel or epoxy-lined rigid tanks. In general, a specific type of package sterilization and aseptic filling and sealing equipment exists for each type of container system.

For ***form-fill-seal processes***, the packaging material arrives at the processing plant as roll stock. This can be mechanically formed into the container, which is then filled and sealed, or it can be thermoformed, ie, a cup or tray shape is drawn in the roll stock, the cavity filled, and a cover is sealed in place, all in an aseptic environment.

Fill-seal systems are those in which preformed containers arrive at the plant. Usually they are sterilized as part of the aseptic system then, after sterilization, they are aseptically filled and sealed.

In ***erect-fill-seal systems***, the packaging material arrives as a knocked down container. In the aseptic machine, it is formed or erected, sterilized, and then aseptically filled and sealed.

Another method is to ***blow-mold*** the container, then fill and seal. The extrusion temperature of the plastic is sufficiently high that a blow-molded container is sterile at the time it is produced. Consequently, the only requirement is to maintain sterility during filling with sterile product and sealing.

The surface of the package and closure and the aseptic transfer zone (the gas atmosphere and the surfaces of that part of the system where product, package, and closure are brought together), must all be sterile. Many methods are used.

In the Dole system, superheated steam is used to sterilize the containers and covers, and to sterilize the filler and closing machine during operation. Superheated steam is not as efficient as saturated steam as a bactericidal agent because it is dry heat. However, if the temperature is high enough, it will sterilize a clean, dry surface.[40,43,72,73] The advantage of superheated steam over saturated steam is that it is at atmospheric pressure, thereby eliminating the necessity of valving the containers into and out of a pressurized sterilization chamber.

Where the containers are made of plastic and/or paper, most aseptic systems use hydrogen peroxide. However, steam may be used to sterilize the metal surfaces that enclose the aseptic transfer zone. Packages and packaging materials also may be sterilized by ionizing radiation or other chemicals. Peracetic acid, ethylene oxide, halogens, ozone, and orthophosphoric acid have all been considered and/or used, singly and in combinations. Surface sterilization was reviewed by Cousin.[36]

Aseptic equipment must be designed so that (1) the designated sterile zone can be sterilized prior to processing, (2) packaging material can be sterilized, (3) the operation produces a shelf-stable, packaged product, and (4) all presterilizing and sterilizing functions are closely controlled. When the packaging material is sterilized, in whole or in part, by immersion in a liquid bactericide, an automatic sensing device must be included to ensure an adequate level of the bactericide.

Air and/or gasses used in the designated sterile zone and in contact with food product, packaging material, and/or sterile surfaces must be (1) approved (FDA approved in the US) for the intended use, and (2) filtered and incinerated, or filtered through at least two separate systems, each capable of producing sterile air.

Improved quality of aseptically processed food products is often achieved by taking advantage of the difference in thermal destruction rates between bacteria and food quality factors. Another advantage is that aseptic containers will usually be less expensive than conventional containers, will often be rectangular in dimension so that they stack more efficiently, and will usually weigh less than a conventional can or glass jar.

The present state of aseptic technology is (1) that there are few problems with acid foods, (2) systems are in place that will handle homogeneous low-acid products,[92] and (3) systems are being constructed, in 1998, for low-acid products containing particulates. However, aseptic is a complex industrial technology where there are still several technological and validation hurdles that need to be addressed before sustained growth of this industry can be assured.[16,30,38,44,77,104,110,114]

3.5.6 Hot Filling

Hot-filled food products with pH <4.6 are heated in some type of continuous system to a temperature and time that are adequate to effect microbial control for the specific product. The hot product is filled into containers and the containers sealed. The containers may only be washed before filling, or they may be washed and decontaminated before filling. After filling and sealing, the containers of hot product may be held before cooling, to effect microbial control of container and closure.[100] Using this system, a product such as tomato juice is heated in a closed system to a temperature of 240°–250°F (115°–121°C), and then cooled to about 210°F (99°C). The product is filled into containers at a temperature at or above 190°F (88°C), the container is then sealed, held hot for 1 to 3 minutes and cooled. The same general procedure is recommended for most fruit juices such as apricot, grapefruit, orange, and pineapple, which are normally heated to about 190°F (88°C) in a plate-type heat exchanger, filled into cans or bottles, making sure that the closing temperature is at least 175°F (79°C), sealed, held for a few minutes, and then rapidly cooled. If glass containers are used, a holding conveyor is required, which is usually part of the cooling system. To minimize thermal shock breakage, the cooler must have a tempering zone where the water temperature is about 130°F (54.5°C) in addition to the final cooling zone where the water temperature is 60°–80°F (15.5°–26.7°C).

An air blast is used to dry jars if they are to be labeled immediately. The product should be cooled to 100°F (38°C) before warehousing. An excellent summary is given by the National Canners Association.[69]

A system named "flash 18" has been developed for filling and sealing containers in a pressurized room held at about 18 psi gauge, making it possible to apply higher temperature, hot fill processing to low-acid foods. In this system, the food may be heated as high as 255°F (124°C) in a heat exchanger, filled, and sealed in metal or glass containers at this temperature in the pressurized room, then rapidly cooled. Heat damage during in-container cooling is only slight compared with heat damage to sensitive foods during in-container heating in large (No. 10) containers. The system has obvious advantages for packing sterilized nonacid foods in large, hermetically sealed containers.

3.6 CONCLUDING REMARKS

In this chapter the kinetics of heat destruction of microorganisms, methods of measuring moist-heat resistance, selecting F_T-values for low-acid canned foods, and the delivery of heat in commercial microbial control processes have been described.

In the the treatment of foods for microbial control, we have a science operation and a technology operation that must be combined in order to deliver safe and stable food. The science was covered in the first part of the chapter and the technology was emphasized in the latter part. It is perhaps important to mention that the scientist seeks to determine the truth regarding an area under study, and usually in a small well-defined area, whereas the technologist is trying to produce safe food in a system where he does not necessarily know the values of all the variables. In the selection and delivery of adequate processes, technologists must know their products and use judgment in selecting the critical parameters. We have tried to include some guidelines in this area. An expanded treatment can be found in Pflug et al.[75,77,78,80]

Appendix 3-A

Definitions

F_T:	***Equivalent heating time at heating medium temperature.*** The equivalent time at the medium heating temperature, T, provided by the heat process calculated using a specified z-value.
F_0:	***Sterilization equivalent process time.*** Number of equivalent minutes at T = 250°F delivered to a container of product calculated using a z-value of 18°F (or at T = 121.1°C with a z-value of 10°C).
L:	***Lethal rate.*** The rate of microbial destruction at temperature T expressed in terms of the reference temperature, T_{ref}. The units of the lethal rates are minutes at T_{ref} per minute at T. $L = 10^{[(T-Tref)/z]}$.
N_0:	***Initial number of microorganisms per unit.*** The initial number of microorganisms per unit, sometimes called the bioburden.
N_U, N_F:	***Number of microorganisms per unit after stress.*** The number of viable microorganisms per unit that survive a heat process of U minutes at T_1 or of F minutes at temperature T.
TDT, F_T:	***Thermal death time.*** The time at temperature T necessary to reduce the number of microorganisms in a homogeneous population by a specified amount. $F_T = Y_n \times D_T$.
U:	***Equivalent minutes at heating-medium temperature.*** Net or equivalent time at the heating-medium temperature, T_1. $U = F(T_1,z)$.
z-value:	***Temperature coefficient of microbial destruction.*** The negative reciprocal of the slope of the TDT, TR, or RKT curves. The number of degrees of temperature change necessary to cause the F-, D-, or RKT-value to change by a factor of 10, measured in degrees F or C.

4.1 INTRODUCTION AND HISTORICAL PERSPECTIVE

Radiation processing is not a new technology and has been used for many years for the sterilization of medical supplies and for the treatment of plastics to improve their properties. The application of the technology for the treatment of food is also not new. A United Kingdom (UK) patent was issued in 1905 for the use of ionizing radiation "to bring about an improvement in the condition of foodstuffs," and in 1921 the US Department of Agriculture (USDA) Bureau of Animal Industry proposed the use of x-rays for inactivating trichinae in pork.[24] However, it was not until the 1950s that sufficient quantities of suitable isotopes were available for the treatment of food. This development, together with the initiation of an "Atoms for Peace" program by the late President D. Eisenhower in 1953, led to an intensified research program to evaluate the potential applications of food irradiation in the 1950s and 1960s in both advanced and developing countries. However, the safety for consumption of irradiated foods became an issue for concern in the late 1950s due to the US Food Additive Amendment of the federal Food, Drug and Cosmetic Act, which classified food irradiation as a "food additive." Such a classification resulted in an international effort to prove the wholesomeness of irradiated food, initially carried out in advanced countries such as the United States (US), the UK, Germany, The Netherlands, and Japan.

In 1970, an International Project in the Field of Food Irradiation (IFIP) was established in Karlsruhe, Germany, under the aegis of the Food and Agricultural Organization of the United Nations (FAO), the International Atomic Energy Agency (IAEA), and the Organization for Economic Cooperation and Development (OECD) with participation by 24 countries, to investigate the wholesomeness of irradiated food. The World Health Organization (WHO) became associated with the International Project in an advisory capacity. This research effort, coordinated by IFIP, generated a significant amount of data on wholesomeness of irradiated food for evaluation by a Joint FAO/IAEA/WHO Expert Committee on the Wholesomeness of Irradiated Food (JECFI), which was convened in 1976 and again in 1980. In October 1980, when the data on long-term animal feeding studies of irradiated food, and on the radiation chemistry of foods and food constituents were available, the JECFI was able to reach a conclusion that "the irradiation of any food commodity up to an overall average dose of 10 kiloGray (kGy) presents no toxicological hazard; hence, toxicological testing of foods so treated is no longer required." The expert committee also found that irradiation up to 10 kGy "introduces no special nutritional or microbiological problems."[1] The conclusions of the JECFI report, along with information available from national expert committees, led the Joint FAO/WHO Codex Alimentarius Commission to adopt the Codex General Standard for Irradiated Foods and the Recommended International Code of Practice for the Operation of Radiation Facilities for the Treatment of Food in 1983.[2] This view was reaffirmed in 1994 by WHO with the statement that "irradiated food produced in accordance with established good manufacturing practices can be considered safe and nutritionally adequate."[8]

These positive conclusions have provided major milestones in the further development of food irradiation. As a result, 38 countries including the US, France, the UK, South Africa, China, The Netherlands, and Thailand have approved the irradiation of many different food items or classes of food[6] (Appendix 4-A). However, because of policy and economic reasons, not all of these countries are using the technology in practice. Currently, 35 countries are using the technology for treating different types of foods (Table 4-1).

The wholesomeness of food irradiated with doses above 10 kGy was evaluated by a Joint FAO/IAEA/

Table 4-1 List of Irradiation Facilities Available for Food Processing

Country	*Location (starting date for food irradiation)*	*Products*
Algeria	Mascara	Potatoes
Argentina	Buenos Aires (1986)	Spices, spinach, cocoa powder
Bangladesh	Chittagong (1993)	Potatoes, onions, dried fish
Belgium	Fleurus (1981)	Spices, dehydrated vegetables, deep frozen foods
Brazil	Sào Paulo (1985)	Spices, dehydrated vegetables
	Piracicaba Manaus	Fruits, vegetables, grain
Canada	Laval (1989)	Spices
Chile	Santiago (1983)	Spices, dehydrated vegetables, onions, potatoes, poultry meat
China	Chengdu (1978)	Spices and vegetable seasonings, Chinese sausage, garlic
	Shanghai (1986)	Apple, potatoes, onions, garlic, dehydrated vegetables
	Zhengzhou (1986)	Garlic, seasonings, sauces
	Nanjing (1987)	Tomatoes
	Jinan (1987)	Not specified
	Lanzhou (1988)	Not specified
	Beijing (1988)	Not specified
	Tienjin (1988)	Not specified
	Daqing (1988)	Not specified
	Jianou (1991)	Not specified
	Beijing (1995)	Rice, garlic, spices
Croatia	Zagreb (1985)	Spices, food ingredients, dried beef noodles
Czech Republic	Prague (1993)	Spices, dry food ingredients
Cuba	Havana (1987)	Potatoes, onions, beans
Denmark	Riso* (1986)	Spices
Finland	Ilomantsi (1986)	Spices
France	Lyon (1982)	Spices
	Paris (1986)	Spices, vegetable seasonings
	Nice (1986)	Spices/herbs
	Vannes* (1987)	Poultry (frozen deboned chicken)
	Marseille (1989)	Spices, vegetable seasonings, dried fruit, frozen frog legs, shrimp, poultry (frozen deboned chicken)
Germany	Munich (1997)	Spices
Hungary	Budapest (1982)	Spices, onions, wine cork, enzyme

Vietnam	Ho Chi Minh City (1999)	Spices, dried herbs
Yugoslavia	Belgrade (1986)	Spices

Note: Facilities underlined are under construction or planned; countries underlined are irradiating food for commercial use. (All facilities use Co-60 as radiation source except those indicated by *, which are electron beam facilities.)

Courtesy of International Atomic Energy Agency, Vienna, Austria.

WHO Study Group in September 1997. Having examined data on toxicological, nutritional, microbiological, and radiation chemistry aspects of foods so treated, the Group concluded that food irradiated to any dose appropriate to achieve the intended technological objective is both safe to consume and nutritionally adequate. There is no need for an upper dose limit to be imposed. Thus, irradiated foods are deemed wholesome throughout the technologically useful dose range below 10 kGy to envisioned doses above 10 kGy.[137]

4.2 IRRADIATION PROCESSING

A commercial irradiation facility consists of an irradiation chamber that contains the source of the ionizing radiation, a conveyor system that passes the products into and out of the radiation chamber, and separate loading and unloading areas and a control unit (Figure 4-1). The major structural difference between this type of plant and other industrial buildings is the thick concrete walls (typically 2 m) that surround the irradiation room. These walls act as a shield and prevent the radiation from penetrating beyond the chamber.

Only certain radiation sources can be used for the treatment of foods. These are the radionuclides cobalt-60 and caesium-137, which emit gamma rays; electron beam machines, which emit electrons with a maximum energy of 10 million electron volts (MeV); and x-ray machines, which have a maximum energy of 5 MeV. The radiation emitted from all the sources is referred to as "ionizing" because the energy is high enough to dislodge electrons from atoms and molecules and to convert them to electrically charged particles called ions. However, the energies from these sources are too low to induce radioactivity in any material, including food. Of the radionuclides, only Co-60 is available in sufficient quantities for commercial irradiation. In the case of the radionuclides, radiation is constantly emitted and, when not in use, the source is stored in a deep (typically 6 m) water pool. Machine sources, however, are electrically operated and can be switched on and off.

The conveyor system, which transports products around the radionuclide source, follows a convoluted pathway to ensure a more even dose distribution. The separate loading and off-loading areas ensure that untreated and treated products are kept separate. The speed of the conveyor system (and hence, the dose delivered) is preselected at the control unit. The unit also allows the monitoring of the radiation source and the processing conditions from outside of the irradiation chamber.

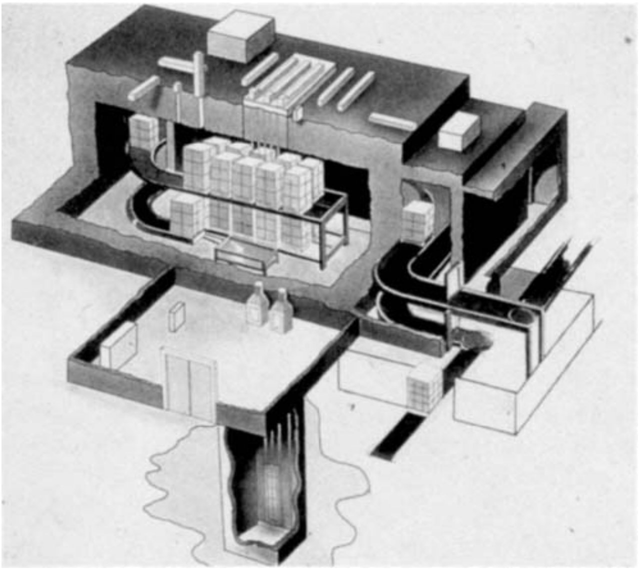

Figure 4-1 Automatic Pallet Irradiation Facility. Courtesy of Gammaster B.V., Ede, The Netherlands.

Worldwide there are approximately 160 commercial gamma irradiation facilities and hundreds of electron accelerator facilities used mainly to process nonfood products. These facilities are strictly monitored to ensure their safe operation and are subject to government legislation and control. Irradiation facilities typically cost 1 million to 3 million US dollars or more depending on size and capacity.[65] Therefore, medical supplies are often sent to a central commercial facility. It is likely that food companies would also use central facilities for the irradiation of their products.

4.3 APPLICATIONS OF FOOD IRRADIATION

Treatment of food with ionizing radiation can produce a wide variety of beneficial effects, including a delay in ripening of fruits and vegetables; inhibition of post-harvest sprouting of tuber and bulb crops; and the destruction of insects, parasites, pathogenic and nonpathogenic bacteria, yeasts, and molds. This chapter is concerned primarily with the microbiological effects of food irradiation. Further information on the other applications can been found elsewhere.[58,132]

The amount of radiation absorbed by a food, the absorbed dose, is measured in grays (Gy), where one gray is equal to the absorption of 1 Joule/kg. In most food applications, the dose required is defined in kilograys (kGy). Irradiation treatments aimed at the inactivation of microorganisms can be divided into three classes:

1. ***Radappertization:*** the treatment of a food with a sufficient minimum dose of irradiation, usually 25 to 45 kGy, to produce a commercially sterile product. This is equivalent to the sterility achieved with heat processing (canning). Foods treated in this way can be stored for several years at ambient temperatures, provided they are not recontaminated. High dose food applications include the provision of sterile diets for immunocompromised individuals. Irradiation sterilized foods have also been used by US astronauts, by defense force personnel, and by specific recreation and sport groups such as hikers, campers, and yachters in South Africa.

2. ***Radicidation:*** the treatment of a food with a dose of irradiation sufficient to reduce the numbers of viable, non–spore-forming pathogenic bacteria to undetectable levels using standard bacteriological procedures. This is equivalent to pasteurization with heat and requires doses of <10 kGy. This treatment will also inactivate foodborne parasites such as tapeworm and trichina in meat.
3. ***Radurization*:** the treatment of a food with a dose of radiation (<10 kGy) sufficient to reduce numbers of spoilage microorganisms and so enhance the keeping quality of foods.

Radicidation and radurization treatments will not kill all microorganisms, therefore, the food will eventually spoil unless preserved in some other way.

4.4 BIOLOGICAL EFFECTS

If the death rate is exponential, the sensitivity of a microorganism to irradiation can be defined as a D_{10}-value, the dose (kGy) required to inactivate 90% of the population. If N_0 is the initial number of the organisms present, and N is the number remaining after irradiation with a dose D then

$$D_{10} = \frac{D}{\log N_0 - \log N}$$

In many cases, a linear relationship is obtained in a semi-logarithmic plot of log survivors against dose, so the D_{10} can be calculated as –1/slope of the regression line. In other cases, there is a "shoulder" at lower doses or a residual "tail" at higher doses. Bacteria exhibiting a shoulder in their inactivation curves possess more than one vital target per cell, while all targets should be hit to inactivate the cell. The shoulder can also represent the ability of an organism to repair some DNA damage so that more than one hit is required to inactivate the cell, while tailing is most often observed in complex media such as fish meal and crabmeat.[86] When the inactivation curves are not linear, it is difficult to accurately estimate a D_{10}-value. Alternatively, the minimum required dose (MRD) to achieve *n* log cycles reduction can therefore be calculated. In practice, the MRD can be the dose of irradiation that, at a given initial contamination level, reduces the final numbers to a nondetectable level, ie, the minimum required dose. This approach has been used to calculate the dose required to achieve a 10^{12} reduction of *Clostridium botulinum* spores in certain foods under specified conditions (see below).

The radiation sensitivities of representative microorganisms are given in Tables 4-2 through 4-5. In general, Gram-negative bacteria are more sensitive than Gram-positive ones and rods are more sensitive than cocci. Yeasts and molds tend to be more resistant than bacteria and bacterial spores are even more resistant. Viruses are generally the most resistant of the microorganisms. Many interacting factors can affect the sensitivity of microorganisms to irradiation and, as illustrated in Table 4-2, this can lead to very different D_{10}-values, depending on the treatment conditions, as illustrated below.

Intracellular factors include the nature and extent of the damage to a vital target, usually DNA, and the ability of the cell to repair this damage. When ionizing radiation is absorbed by any living biological system, there is the possibility that it will act directly on the DNA and initiate a chain of events, which may ultimately lead to cell death. This effect can cause single and double stranded breaks in the DNA within the cell. Most microorganisms have the ability to repair at least some DNA damage and this in part is reflected in their radiation resistance.[84] Some bacteria, such as *Deinococcus radiodurans* and *Deinobacter grandis* have developed particularly extensive repair mechanisms and are extremely radiation resistant. However, these bacteria do not appear to have any public health significance and are not important in causing spoilage. Alternatively, the radiation may interact with other molecules in the cell, particularly water, to produce highly reactive entities such as the hydrated electron, ·OH, ·H, H_2O_2, and H_3O^+, which can damage the DNA. These intermediates are very short lived and interact with the chemical components of the food and produce stable end-products. The end-products are similar to those found naturally in foods or to compounds produced by heat processing. This indirect effect is of most importance in vegetative cells because they have a relatively high water content.[24]

Viruses have relatively little nuclear material and are orders of magnitude smaller than bacteria and so, being smaller "targets," are relatively resistant to irradiation (have higher D_{10}-values). This also explains why bacteria are more resistant to radiation than protozoa, parasites, and insects. The DNA in mammalian cells contain much more genetic information than these organisms and is correspondingly larger and more sensitive to radiation. The structural arrangement of the DNA itself can also affect radiation sensitivity. Bacterial cells, which are actively dividing (in the exponential phase of growth), are usually more sensitive than those in the lag or stationary phases.[56]

Table 4-2 Radiation D_{10}-Values (kGy) for Bacteria

Organism	D_{10}-*Value (kGy)*	*Substrate*	*Temperature (°C)*	*Atmosphere and Other Remarks*	*Reference*

Vibrio vulnificus	0.30	shrimp paste	–20	vacuum	105
Yersinia enterocolitica	0.20	beef	25	air	31
	0.39	beef	–30		
	0.10–0.20	beef	18–20	air	122
	0.16–0.20	pork	10	air	41
	0.18–0.19	pork		25% CO_2; 75% N_2	

The radiation sensitivity of microorganisms also depends on extracellular conditions such as the nature of the substrate, temperature, and atmosphere during irradiation. Proteins can exert a protective effect on microorganisms. This is because of the presence of free radical scavengers, such as sulphydryl groups, which "mop up" water and oxygen radicals. For example, it has been reported that *Salmonella enteritidis* has a D_{10} of 0.70 kGy and 0.49 kGy in low-fat and high-fat beef, respectively.[79] Assuming that low fat means high protein, then it is possible that the radical scavenging properties of the protein in the low-fat, high-protein beef gave higher protection to the pathogens. For this reason, it is good practice to determine the radiation sensitivities of microorganisms in the actual foods of interest rather than extrapolate data from one type of food to another. If the food has a high water content, then the indirect action of radiation is important, and the bacteria have a lower D_{10}-value than in dry foods. Therefore, higher doses are generally needed to produce the desired microbial kill in dry foods such as spices. A similar argument applies to frozen foods. The water phase is immobilized so the radicals are unable to move and cause indirect damage. Again, higher doses are needed to produce the same microbial kill as in nonfrozen products.[124] The D_{10} of *Escherichia coli* O157:H7 in chicken meat was found to be 0.27 kGy at +5°C and 0.42 kGy at –5°C.[125] Such effects must be taken into account when deciding on an effective radiation dose.

The presence of oxygen generally increases radiation sensitivity. The oxygen molecule has unpaired electrons, and it can add on to many radicals, thereby preventing radical recombination and dimerization. Thus, the presence of oxygen can enhance the indirect action of radiation and result in a lower D_{10}-value. *S. senftenberg* in phosphate buffered saline at room temperature was reported to have a D_{10}-value of 0.13 kGy in aerobic conditions and 0.39 kGy under anoxic conditions. Similarly, *S. typhimurium* had an aerobic D_{10}-value of 0.21 kGy and 0.62 kGy under anoxic conditions.[129] However, the presence of O_2 during irradiation can also cause undesirable changes in sensory properties of the food, such as the oxidation of lipids. This has led to studies of the inactivation achieved in modified atmospheres. For example, some lactobacilli are reported to have lower D_{10}-values when irradiated in 100% CO_2 compared to air, vacuum, or N_2.[48] Studies on the outgrowth of *C. botulinum* type A and B spores and subsequent botulinum toxin production have also shown that low dose irradiation in the absence of O_2 act synergistically to delay toxin production in pork even at a moderate abuse storage temperatures of 15°C.[67]

The microorganisms that survive the irradiation process are likely to be damaged. In one study *Listeria monocytogenes* was inoculated into raw, sterile poultry meat at high initial levels so that detectable numbers would survive the irradiation treatment. The recovery and growth of the surviving cells was monitored during storage at different temperatures. The lag phase duration at 6°C was 1 day in unirradiated samples, 10 days in samples irradiated to 1 kGy, and 15 days in samples irradiated to 2.5 kGy. It was concluded that even if low numbers of *L. monocytogenes* were to survive irradiation treatment, the time required to recover from the irradiation damage would be significant, and growth of this pathogen would not be a problem during the shelf life of the poultry meat.[102]

The ultimate survival of damaged cells depends on postirradiation conditions. Thus, in order to get a valid estimate of survivors, the composition of the plating medium is important. Nutritionally simple media are better than rich media for the recovery of damaged cells.[84] Selective media may not allow all damaged cells to grow, so cells can appear to be more radiation sensitive than when recovered on nonselective media. For example, the D_{10} for *L. monocytogenes* in poultry meat was reported as 0.64 kGy when cells were enumerated on tryptone soya yeast agar and 0.52 kGy on the Listeria selective agar (Oxford formulation).[100] Similarly a suboptimal incubation temperature is better than the optimal. These conditions reduce growth rate and allow the cells time to repair damage.

4.5 IMPROVEMENT IN FOOD SAFETY

It is estimated that the biological contamination of food and water supplies is causing 1 billion cases of disease as well as about 5 million deaths annually.[59] Many of these cases occur in developing countries and are related to infant diarrhea, but industrialized countries also have significant levels of foodborne disease. The Centers for Disease Control and Prevention have estimated that the number of cases of salmonellosis in the US is between 800,000 and 4 million annually.[5] It has been estimated that only 10% of cases of foodborne disease are ever reported so the true figure is likely to be much higher.[106] An upward trend in the number of cases has been found in many countries. The majority of cases are due to either *Salmonella* or *Campylobacter* species. Foodborne cases from other pathogens such as *L. monocytogenes* and *E. coli* O157:H7, although relatively unimportant numerically, are also causing concern due to the high morbidity and mortality resulting from the illnesses they cause.[26]

The first of the 10 World Health Organization (WHO) Golden Rules for Safe Food Preparation advises the consumer to purchase foods processed for safety.[59] Examples quoted include the recommendation to consumers to buy pasteurized as opposed to raw milk and, if they have a choice, to select fresh or frozen chickens that have been treated with irradiation. Only 1 of the 10 rules refers to irradiation, so it is obvious that this technology cannot be a panacea to all problems of food safety but the WHO stresses that it makes a significant contribution.

4.5.1 Pathogenic Non–Spore-Forming Bacteria

Vibrio species and *Aeromonas hydrophila* are among the most radiation sensitive of the vegetative pathogens (Table 4-2). *V. parahaemolyticus* was found to have a D_{10}-value of 0.06 in frozen shrimp homogenate.[12] A dose of 1.0 kGy would therefore give at least a 10^{15} reduction in numbers. Palumbo et al.[97] reported D_{10}-values of 0.14 to 0.19 kGy for five strains of psychrotrophic *A. hydrophila* in ground beef irradiated at 2°C. No significant differences in radiation sensitivity were observed between stationary and logarithmic phase cells.

Yersinia enterocolitica is also very sensitive to irradiation with D_{10}-values of 0.10 to 0.20 kGy when treated in unfrozen foods. As expected, it is more resistant at lower temperatures. For example, in beef at 25°C, the D_{10} was 0.20 kGy compared to 0.39 kGy at –30°C.[31] *Campylobacter* species were found to have similar D_{10}-values to *Y. enterocolitica*, although there were significant differences in the radiation sensitivities between different *Campylobacter* species and within strains of the same species when treated in poultry meat at refrigeration temperatures.[101] However, even the most resistant strain, a pork liver isolate of *C. coli*, with a D_{10}-value of 0.25 kGy, was more sensitive than *S. typhimurium* and *L. monocytogenes* irradiated in poultry meat under similar conditions.

Undercooked hamburger meat and dairy products made from unpasteurized milk have been linked to outbreaks of hemorrhagic diarrhea due to the presence of *E. coli* O157:H7 (see Chapter 43). The organism has also been isolated from raw beef, poultry, pork, and lamb.[27] *E. coli* O157:H7 is relatively sensitive to radiation with D_{10}-values of approximately 0.27 kGy in chilled beef and chicken and 0.3 to 0.45 kGy in meats irradiated at –5° to –15°C.[22,125] Irradiation would, therefore, be an effective method to control this pathogen.

Foods implicated in intoxications due to *Staphylococcus aureus* are frequently cooked, or otherwise treated, for example with salt, so that the competitive microflora has been removed or inactivated. They become contaminated with the pathogen as a result of manual handling and, if subjected to temperature abuse, enterotoxin can be formed during storage. For example, the components of cook-chill ready meals are usually prepared individually, manually portioned and then stored at 3°C for up to 5 days (including day of production and consumption). If the meal components are contaminated with *S. aureus* during portioning, and temperature control is not strictly observed, the potential for toxin formation exists. It has been proposed that irradiation of the prepared meals, after portioning, would be an effective way of ensuring products free from *S. aureus* and other pathogens.[80] A dose of 2 kGy was found to be sufficient to ensure the safety of a roast beef ready meal without significantly affecting the sensory quality. However, irradiation should not be used as a substitute for Good Manufacturing Practice and only foods of good microbial quality should be irradiated. No pathogen should be present initially in meals at levels greater than about 100 g^{-1}.[4] Staphylococcal enterotoxin itself is extremely resistant to irradiation and heat. In a 15% ground beef slurry, 16% to 26% residual staphylococcal enterotoxin activity could be detected after a dose of 23.7 kGy.[108]

Salmonella species and *L. monocytogenes* are the most radiation resistant of the common vegetative pathogens with typical D_{10}-values of 0.50–1 kGy, depending on the substrate and radiation conditions (Table 4-2). Thus, doses recommended to give a significant reduction in numbers of these pathogens from foods will also be appropriate for other vegetative pathogens. For example, a dose of 3.0 kGy applied to fresh, chilled poultry meat would be expected to give at least a 10^4 reduction in numbers of *Salmonella* spp, and *L. monocytogenes*, a 10^9 reduction in *E. coli* O157:H7, and a 10^{12} reduction in *Campylobacter* species and *Y. enterocolitica*. It has been reported that Camembert cheese made from unpasteurized milk can also be successfully irradiated to 2.5 kGy, sufficient to give a significant reduction in numbers of *L. monocytogenes* and *Salmonella* species, provided that the storage temperature and ripening conditions are carefully controlled.[17] This is contrary to the idea that fatty foods, such as some fish and dairy products, are unsuitable for treatment due to the radiation-induced oxidation of the fats.

4.5.2 Pathogenic Spore-Forming Bacteria

The endospores of spore-forming bacteria are more resistant to most preservation treatments, including irradiation, than vegetative cells. Spores of *C. botulinum* are of most concern in shelf-stable foods. In thermal sterilization, the 12D concept is used to ensure foods are processed for safety. If this is applied to radappertized foods, then the dose must be high enough to reduce viable spores of the most resistant strain of *C. botulinum* by a factor of 10^{12}. Type A and B spores are regarded as being the most resistant of the *C. botulinum* spores to radiation while type E are most sensitive.[132] Thus, the MRD would be 12 times the D_{10}-value of the most resistant type A spore. Using the examples given in Table 4-2 for beef, this would be equivalent to a dose of 43.2 kGy at 25°C, 46.2 kGy at 0°C, and 52.08 kGy at –50°C. However, the theoretically determined MRD may not be what is required in practice.

In many cases there is not a simple straight-line relationship between dose and the logarithm of the surviving fraction of spores. For example, there may be a "shoulder" at the low dose end of the curve and a resistant "tail" at the high dose end.[86] D_{10}-values calculated from the linear portion of the curve will then not reflect the true resistance of the spores. Radappertized foods are frequently given a mild heat treatment sufficient to inactivate enzymes, and additional preservatives such as salt or nitrite may be present, depending on the product. All of these will influence the survival of the spores or their ability to germinate and produce toxin, and have to be taken into account when determining the radiation MRD. For these reasons, inoculated pack studies containing spores in the food of interest and prepared under specific conditions can be used instead of theoretical D_{10} calculations. Using this technique, 12D values have been calculated for various foods. For example, the MRD for beef was found to be 41.2 kGy, 26.9 kGy for corned beef, 43.7 kGy for pork, and 31.4 kGy for ham.[57] These values were calculated using a specific preparation technique, which included an enzyme-inactivating heat treatment to an internal temperature of 70°–80°C, vacuum packaging, and an irradiation temperature of –30°C. The addition of salt and nitrate and/or nitrite can influence the survival of the spores as can been seen in the different MRDs required for the cured and uncured meats.

Although the spores are generally present in low numbers, the potential problem of *C. botulinum* may also exist in foods treated with low doses of radiation. When assessing the botulinum risk in these foods, factors such as the probability of spores being present in the product prior to treatment, the dose to be applied, and the likelihood of removing sufficient spoilage microorganisms before toxin is elaborated, particularly if the product suffers temperature abuse, have to be considered. The possibility that the removal of the more radiation-sensitive microflora may, because of the reduced competition, encourage the growth of and toxin production by *C. botulinum* has been investigated. Type E and some of the nonproteolytic type B spores are of particular concern as they can grow and produce toxin in foods at temperatures as low as 3.3°C (Chapter 41). Type E *C. botulinum* is most frequently associated with fish and fishery products although the incidence is variable depending on geographical location.[132] The issue of microbiological safety which arises is whether recognizable sensory spoilage occurs prior to toxin formation in irradiated products. This question is not unique to irradiation but is also relevant to other nonsterilizing preservation treatments, such as the vacuum packaging of smoked fish or heat pasteurized crab meat. When making recommendations for the irradiation of fishery products it is clear that a number of factors must be considered. Some species of fish seem to support the growth of and toxin production by *C. botulinum* type E better than others. For example fatty fish contain ribose and glucose, which are essential for the low temperature growth of *C. botulinum* type E.[132] Exclusion of O_2, through vacuum packaging, may be desirable to reduce rancidity development in fatty fish. However, it also prevents the growth of aerobic spoilage bacteria and encourages the growth of anaerobes, including *C. botulinum*. The initial level of spores can have a significant effect on the time to toxin development. Many laboratory experiments used inoculation levels many orders of magnitude higher than would be encountered naturally. It has been shown that the time required for toxin production increases significantly as the spore population is decreased.[132] In many instances, temperature control below 3.3°C is an important safety feature.

In a series of experiments, fish fillets of different species were inoculated with *C. botulinum* type E and stored under various combinations of packaging, irradiation dose, and storage temperature. The samples were analyzed periodically for toxin production and spoilage off-odors.[30] It was found that the storage temperature had a significant effect on the results. In the case of haddock fillets, at 5.6°C toxin production always lagged behind spoilage by a substantial margin, irrespective of inoculum level (up to 10^4 spores g^{-1}) and irradiation dose (up to 2 kGy). At 7.8°C, however, the safety margin between spoilage and toxin formation was reduced at 2 kGy with 10^2 spores g^{-1}, and with a higher inoculum of 10^4 spores g^{-1}, toxin production preceded spoilage. In this case, packaging the fillets in O_2-permeable or impermeable film did not influence the results. When the experiment was repeated using petrale sole fillets (initial inoculum level = 10^2 spores g^{-1}), in impermeable film, it was found that at 3.3°C there was a large margin of safety between the appearance of spoilage odors and toxin production. However, at 5.6°C and 2 kGy, toxin was present before obvious spoilage. It would therefore appear that petrale sole is a better substrate than haddock for toxin production by *C. botulinum* type E.

In North America, the incidence of *C. botulinum* in red meat is generally low with an estimated 0.04 to 2.18 spores kg^{-1}.[51] The incidence in Europe appears to be higher and nonproteolytic type B is more common.[25] The incidence of *C. botulinum* in poultry meat is also considered to be extremely low and poultry products are very rarely associated with human botulism. However, the possibility that type E spores may be present, as a result of fish meal being included in the poultry diet, has also been considered. It has been shown that when poultry skin, moistened with poultry exudate, was inoculated with type E spores and irradiated to 3 kGy, the *C. botulinum* survivors could not compete with the natural surviving microflora. The samples were stored at 10°C and 30°C and spoilage off-odors were observed before toxin was produced.[35] In another study,[127] vacuum canned commercial mechanically deboned poultry meat was inoculated with 20 strains of *C. botulinum* type A and proteolytic B spores (400 g^{-1} meat). Samples were either not irradiated or irradiated at 5°C to 1.5 or 3.0 kGy and stored at 5°C for 0, 2, and 4 weeks. Toxin was not detected in any of the samples, although all became toxic within 18 hours at 28°C. The aerobic and/or facultative mesophilic counts reached the designated spoilage level of 10^7 cfu g^{-1} at 2 weeks in the control samples, between 2 and 4 weeks in the 1.5 kGy samples, and not at all after 4 weeks in the 3.0 kGy samples during storage at 15° and 35°C. Only the unirradiated samples were considered to have a spoilage odor after 4 weeks. Gram-positive bacteria, mainly streptococci, dominated the irradiated samples during storage and would likely give an acid-sour odor upon opening the vacuum packages.

It is well established that, like staphylococcal enterotoxin, extremely high doses of irradiation are required to inactivate botulinum toxin in food. The botulinum toxin activity remaining in ground beef mixtures irradiated to 25 kGy increased from 1% to 30% as the proportion of ground beef increased from 15% to 100%.[131] Rose et al.[108] also found that increased concentrations of beef slurry conferred increased protection to botulinum and staphylococcal toxins against irradiation.

Clostridium perfringens may be a contaminant of meat and poultry. The spores are resistant to irradiation and the vegetative cells appear to be more resistant than *Salmonella* species, when irradiated in meat substrates (Table 4-2). Radicidation doses proposed for the elimination of other vegetative pathogens may not give sufficient inactivation of this pathogen. Storage below 15°C is therefore necessary for controlling the growth of *C. perfringens* in irradiated foods, as is recommended for other nonsterilizing preservation treatments.

It has been reported that the radiation resistance of *B. cereus* spores is not affected by temperature, desiccation, or suspending medium to the same extent as vegetative cells.[75] A study of the effect of temperature during irradiation found that stationary phase vegetative *B. cereus* cells inoculated into sterile beef and irradiated to 3 kGy decreased in numbers by 4.20, 5.27, and 5.72 $\log_{10}$ units at -20°, 0°, and 20°C. However, irradiation temperature was found to have no significant effect on spore survival.[126] A comparison of the radiation response of six strains of *B. cereus* inoculated into pre-irradiation sterilized ground beef, pork, chicken, turkey, and a heat sterilized beef gravy was then made. The D_{10}-values obtained in mechanically deboned chicken for one strain were 0.18 (log phase), 0.45 (stationary phase), and 2.56 kGy (spores). Spores for all strains were more resistant in beef, pork, and gravy than in poultry meats. In another study[45] irradiation of roast beef and gravy to 2 kGy at 4°C resulted in a 10^3 to 10^4 reduction in numbers of vegetative *B. cereus* cells. During subsequent storage at an abuse temperature of 15°C, the surviving cells grew slower, possibly as a result of irradiation injury, and toxin production was inhibited although toxin was found in the unirradiated controls. Toxin was found in both nonirradiated and irradiated samples stored at 22°C.

4.5.3 Viruses

Food virology is a relatively new science, and there is still much research needed to determine the role of viruses in foodborne disease (Chapter 52). However, outbreaks of foodborne illness have been associated with viruses such as Norwalk and hepatitis A.[11] The inactivation rates of viruses by irradiation are exponential functions of the radiation dose.[24] D_{10}-values tend to be high, typically 2–7 kGy at irradiation temperatures up to 20°C. The D_{10}-value increases further as the temperature during irradiation decreases (Table 4-3). Thus, irradiation doses below 10 kGy will not give an adequate reduction in the numbers. Foods given low doses of irradiation may still contain infectious viruses. This is not unique as other nonsterilizing preservation treatments, such as freezing, will also allow the survival of viruses. Viruses can be inactivated by heat[56] so the combination of heating with irradiation can be used successfully.

4.5.4 Parasites

Foodborne parasitic infections are widespread in both advanced and developing countries but are often not recognized by health and regulatory authorities. These infections are frequently associated with consuming raw or underprocessed food of animal origin, and the resulting economic losses can be enormous (Chapters 50 and 51). For example, the cost of foodborne toxoplasmosis, caused by *Toxoplasma gondii*, in the US is estimated to be up to 2.6 billion dollars a year.[107] Worldwide, the rates of congenital toxoplasmosis infection are estimated at 0.1% to 0.8% of live births or up to about 1 million infected babies born each year.[14] Another parasitic disease caused by the liver fluke *Opisthorchis viverrini*, through consumption of raw freshwater fish, results in an estimated economic loss of up to 99 million dollars per annum to the society in Thailand.[74]

Foodborne parasites, in general, are more radiation sensitive than pathogenic microorganisms. Thus, radiation doses required to ensure the microbiological safety of food of animal origin appear to be adequate for controlling foodborne parasites as well. As foodborne parasitic infections normally occur in rural areas, it may be difficult to demonstrate the cost-effectiveness of irradiation as a public health control measure. However, where irradiation is used to ensure microbiological safety of food, it could be demonstrated that such a measure will also be effective for controlling infections caused by foodborne parasites.

It should be noted that radiation doses required for controlling infection of foodborne parasites do not necessarily kill them outright. In general, a radiation dose below 1 kGy will prevent the most infective stage of parasites from infecting humans. For example, a dose of approximately 0.5 kGy will prevent the tapeworms *Taenia saginata* and *T. solium* from developing the segments required for infection. A

Table 4-3 D_{10}-Values (kGy) of Viruses

Organism	*D_{10}-Value (kGy)*	*Substrate*	*Temperature (°C)*	*Atmosphere and Other Remarks*	*Reference*
Hepatitis A	2.02	clams/oyster		air	76
Poliovirus	3.1	oysters		air	76
	3.0	fish fillets		air	50
Rotavirus	2.4	clams/oysters		air	76
Coxsackie virus	7.5	raw beef	–30	air	121
	6.8		–90		
	6.8	cooked beef	–30		
	8.1		–90		

minimum dose of 0.3 kGy will sterilize the most infective stage of the nematode *Trichinella spiralis* without killing it. Radiation doses required for controlling infections of foodborne parasites are summarized in Table 4-4.

4.6 EXTENSION OF SHELF LIFE

On a global scale, between a quarter and a half of the world's food supply is lost post-harvest as a result of spoilage, insect infestation, and bacterial and fungal attack.[3] Irradiation is one method of reducing such losses.

4.6.1 Nonpathogenic Bacteria

Irradiation, like any other nonsterilizing treatment, has a selective effect on the heterogeneous microflora of foods. Many of the common spoilage microorganisms such as *Pseudomonas* species, and other aerobic Gram-negative bacteria are sensitive to irradiation, with D_{10}-values below 0.2 kGy (Table 4-2). Therefore, irradiation doses aimed at improving food safety will also be effective at reducing numbers of spoilage organisms, resulting in an extension of shelf life, particularly of flesh foods. Organisms in the *Moraxella/Acinetobacter* group are unusual in that, although they are Gram-negative, many of them are relatively resistant to irradiation, with D_{10}-values similar to yeasts (Tables 4-2 and 4-5). In general, however, there is a shift to a predominately Gram-positive microflora after irradiation.

Lactic acid bacteria are relatively resistant to irradiation (Table 4-2). Although they are generally present as a minor component of unirradiated fresh meats, they tend to dominate the microflora of irradiated meats, especially if packaged under a vacuum or in a CO_2-enriched atmosphere.[52] *Lactobacillus sake* and *L. curvatus* have been found to be the dominant types in both irradiated beef and pork.[42,48] Unlike most other bacteria, *L. sake* is reported to be more radiation resistant in the log growth phase than in the stationary phase, and more resistant when irradiated in N_2 or under vacuum than under CO_2.[48] The development of a lactic microflora may be desirable as it can give additional consumer protection. The lactic acid bacteria produce acidic metabolites that lower the pH of the environment, thus

Table 4-4 Effective Radiation Doses for Parasites

Parasite	*Minimum Effective Dose (kGy)*	*Bioassay Model*	*Reference*
Protozoa			
Toxoplasma gondii	0.5	mice, cats	28
	0.7	mice,cats	136
	0.45–0.6	mice, cats	118

Table 4-5 Inactivation Dose (kGy) for Yeasts and Molds

Microorganism	*Irradiation Dose (kGy)*	*Substrate*	*Temperature (°C)*	*Atmosphere and Other Remarks*	*Reference*
Candida zeylanoides	0.68	chicken skin	10	air, calculated as D_{10}-value	53
Cryptococcus albidus	2.5	chicken skin	10	air, calculated as D_{10}-value	53
Cryptococcus albidus	10	grape juice	ambient	value is dose needed to prevent growth of 0.6–2.5 × 10^6 cells ml^{-1}	34
Sporobolomyces roseus	0.75	phosphate buffered saline	4	air, calculated as D_{10}-value	81
Sporobolomyces pararoseus	5.0	nutrient broth	ambient	value is dose needed to prevent growth of 0.6–2.5 × 10^6 cells ml^{-1}	34
Saccharomyces cerevisiae	18	grape juice	ambient	value is dose needed to prevent growth of 1.5–3.0 × 10^6 cells ml^{-1}	33
Torulopsis stellata	10	grape juice	ambient	value is dose needed to prevent growth of 1.5–3.0 × 10^6 cells ml^{-1}	33
Penicillium expansum	0.32	grain	10	air, calculated as D_{10}-value	93
Penicillium viridicatum	1.4	0.1% peptone + 0.1% Tween 80	ambient	value is dose needed to prevent growth of 4 × 10^6 conidia ml^{-1}	88
Aspergillus flavus	1.7	0.1% peptone + 0.1% Tween 80	ambient	value is dose needed to prevent growth of 4 × 10^6 conidia ml^{-1}	88
Aspergillus ochraceus	0.44	grain	10	air, calculated as D_{10}-value	93

discouraging the growth of other bacteria, including spore-forming and vegetative pathogens.[56] Many strains have also been shown to produce bacteriocins and other antimicrobial substances, which can retard the growth of pathogens.

Niemand et al.[91] reported that a dose of 2.5 kGy resulted in a greater than 3 $\log_{10}$ reduction in the total aerobic and anaerobic plate counts in chilled beef. It was observed that the lactic acid bacteria dominated the microflora in both air and vacuum irradiated packs and that Enterobacteriaceae, *Brochothrix thermosphacta* and the pseudomonads were not detected. The shelf life of the beef stored at 4°C was reported to be "well over 9 days when evaluated by bacteriological criteria."

Similarly, in another study, the microflora of irradiated (1.75 kGy) pork packaged in a modified atmosphere (MA) of 25% CO_2:75% N_2 was almost exclusively composed of lactic acid bacteria, predominantly *Lactobacillus* species after storage at 4°C.[40] Later studies confirmed that many of these *Lactobacillus* species were capable of producing bacteriocins active against *L. monocytogenes.*[19] The shelf life of the irradiated MA packed pork, as assessed by a trained sensory panel, was found to be 12 days at 4°C, compared to 8 days in the MA without irradiation, and 2 days if packaged in air without irradiation.[40]

An irradiation dose of 2.5 to 5 kGy has been recommended for poultry carcasses.[60,70] This should not significantly affect the organoleptic quality of the product but can extend the shelf life at chill temperatures from 6 to 14 days and greatly reduce the number of pathogens.[87] A dose of 2.5 kGy was also reported to give a 4-week extension at 0°–3°C to the shelf life of chilled lamb pieces.[103]

4.6.2 Yeasts

Yeasts reproduce primarily by budding. Radiation can kill the cells outright but lower doses are sufficient to prevent them from reproducing. Nonlinear curves, with an initial shoulder, are often found when plotting $\log_{10}$ numbers of survivors against dose.[81] For these reasons, the radiation sensitivity of yeasts may be expressed as the minimum required dose or effective dose rather than as a D_{10}-value.[132] The effective dose is related to the size of the initial population, and this should be stated when quoting such values (Table 4-5).

In general, yeasts are more resistant to irradiation than bacteria. If it is assumed that an inactivation dose of 18 kGy for *Saccharomyces cerevisiae* reduces 3 × 10^6 cells to zero (Table 4-5), then this corresponds to a D_{10}-value of 2.8 kGy, similar to that of *C. botulinum* type E spores. An irradiation dose of 2.5 kGy reduced numbers of yeasts on chicken breasts[70] from 5 × 10^2 cfu g^{-1} to 3.2 × 10 cfu g^{-1} and 1.5 kGy reduced numbers of yeasts in British sausage by 1 $\log_{10}$, while a dose of 3 kGy resulted in almost a 2 $\log_{10}$ reduction.[81] *Sporobolomyces roseus* was found to be more radiation sensitive than *Debaryomyces* *hansenii,* which in turn was more sensitive than *Candida zeylanoides* and *Trichosporon cutaneum.*

Yeasts have the potential to contaminate all foods but are generally only significant in the spoilage of fruit and vegetables, cereal grains, legumes, and baked products.[132] They are usually not a problem in meats and poultry because initial numbers are low and their slow growth rates at refrigeration temperatures prevent them from competing effectively with psychrotrophic bacteria.[136] However, yeasts tend to be more resistant to irradiation than bacteria, and they can be important in the spoilage of irradiated meat and meat products, such as sausages, stored at chill temperatures.

4.6.3 Fungi

Fungi may produce both hyphae and spores, and it is difficult to determine cell numbers and therefore difficult to determine radiation D_{10}-values. As with yeasts, one alternative is to report minimum required dose levels or the dose required to suppress the growth of a known number of cells (Table 4-5). *Fusarium* species and *Alternaria* species are generally more resistant to irradiation than *Penicillium* species and *Aspergillus* species.[93] *Target theory* models have been developed to explain irradiation resistance. The *multiple hit* theory assumes that the target, usually DNA, must be hit a number of times before the organism is destroyed. Spores of *Fusarium* species and *Alternaria* species are multicellular and, therefore, from the multiple hit theory, if one cell escapes damage the spore can still have the ability to germinate. This is in contrast to the unicellarity of *Aspergillus* species and *Penicillium* species.

Fungal spoilage can be a problem in most fruits. Fresh strawberries normally have a short shelf life due to the growth of microorganisms such as *Botrytis, Rhizopus,* and *Mucor* species.[82] A dose of 2 kGy with storage at 5°C can control fungal growth and give a shelf life of 14 days compared to <7 days in the unirradiated controls. Similarly, fungal spoilage in other fruits such as citrus, pomme fruits, and stone fruits can be controlled by 1 or 2 kGy.[132] However, sensory changes can occur in some fruits, even at these doses. The problem can be solved by combining low dose irradiation with a hot water dip. For example, some varieties of mangoes cannot be irradiated successfully above 1 kGy, which is insufficient to inhibit fungal spoilage. An effective treatment is a combination of irradiation to 0.75 kGy with a 5-minute dip in water at 50° or 55°C. This combination along with transport and storage at 11°C gives a shelf life of around 30 days, of which 1 week can be at ambient temperature. If applied to mature green mangoes, the combination will not only control fungal decay but will also delay ripening and inactivate the mango weevil, if present.[133]

Low dose irradiation of grains, usually below 1 kGy, is also used as a method for insect disinfestation but can, in addition, reduce the fungal population. However, there has been some debate regarding the effects of irradiation on fungal metabolism, particularly on mycotoxin production. Some reports indicate that irradiation can enhance the production of aflatoxin[10,104] while others suggest that it has no effect[15,115] or decreases it.[21] Similarly, ochratoxin A production by *A. ochraceus* was found to have increased in some experiments and decreased in others.[98] There are several explanations for the variability of the results. It is known that inoculum size has a significant effect on mycotoxin production. It has been demonstrated that a 10^4 reduction in the number of spores, caused by simple dilution or by irradiation, resulted in a two-fold increase in aflatoxin production by *A. parasiticus*[114] and up to a 12-fold increase in aflatoxin production by *A. flavus.*[92] Thus, it appears that toxin production is suppressed when the number of inoculated spores per unit volume of substrate exceeds a certain optimum, perhaps due to a changed ratio with spoilage organisms. Many of the experiments in which irradiation appeared to enhance aflatoxin production used large spore inocula, so control samples, with no dilution effect due to irradiation, may have exhibited suppressed mycotoxin production due to the inocula size.

In a field trial in India, naturally contaminated wheat was stored at 90% relative humidity at 28°C, conditions not unusual in that continent. The same or lower levels of aflatoxin production were found in the irradiated (0.2 kGy) samples compared to unirradiated controls.[15] In another study, the effects of irradiation (2 kGy) on ochratoxin A production by *A. alutaceus* were monitored.[16] The authors reported that ochratoxin A production was diminished if the fungus was inoculated into the grain prior to irradiation (2 kGy). However, if the grain was irradiated first and then inoculated with *A. alutaceus*, then toxin production was enhanced suggesting that reduction or elimination of competitive microflora allowed greater production of the mycotoxin than would occur in the presence of effective competition. The effects of repeated cycles of sublethal irradiation on several strains of *A. flavus* has been studied.[36] It was found that such treatment more frequently led to a complete loss of, or decrease in, aflatoxin production than to an increase.

As with the other microbial toxins, the mycotoxins are themselves resistant to irradiation. Aflatoxins in rice were found to be destroyed exponentially by irradiation, with aflatoxin B_1 and G_1 being more radiation sensitive than B_2 and G_2.[64] However, a dose of greater than 500 kGy was required to destroy even the most radiation sensitive, aflatoxin G_1. Ochratoxin, at concentrations of 5, 10, and 20 $\mu g\ ml^{-1}$ was stable to an irradiation dose of 75 kGy.[98] The trichothecenes deoxynivalenol and 3-acetyl deoxynivalenol also required greater than 50 kGy for their destruction in grains.[94]

4.7 COMBINATION TREATMENTS

Although irradiation is a very potent and useful antimicrobial process in its own right, the dose that can be applied to a particular food, and hence the extent of the antimicrobial kill, can be limited by undesirable sensory changes. The threshold dose above which these changes can be detected varies with different foods. For example a slight "irradiation flavor" was detected at 1.75 kGy in pork, at 2.5 kGy in chicken, lobster, beef, and shrimp, and at 6.25 kGy in lamb.[120] One approach to achieving optimum quality in both microbial and sensory terms is to use irradiation in combination with other preservation techniques. The use of combination treatments can result in enhanced preservative action and/or reduction in severity of one or all the treatments.

The combination of irradiation with heat was first suggested in the 1950s when synergistic effects were observed with a variety of biological systems including bacteria. More recently it has been suggested that irradiation followed by heating could be used to control spoilage and increase the microbiological safety of certain foods.[32] The order of the application can affect the level of microbial inactivation achieved. In most instances, the preferred order is first irradiation and then heating. An irradiation dose of 5 kGy is sufficient to sensitize clostridial spores to subsequent heating.[62] This was found to be of value in heat-treated spiced meats. Spores, frequently natural contaminants of spices, were sensitized during irradiation of the spices. The spices were then incorporated into luncheon meat, which was canned and heat treated to give a commercially sterile product. The heat treatment required in the canning process was less (the F_0 was reduced from 4.5 to 3.0) as the spores were more heat sensitive. This reduction in heating was reported to give better product quality and a saving in energy.

Irradiation can also sensitize vegetative cells to subsequent heating. Thayer et al.[128] investigated the effects of heat and ionizing radiation on *S. typhimurium* in mechanically deboned chicken meat and reported that irradiation to a dose of 0.9 kGy caused heat sensitization in the pathogen. The radiation-induced heat sensitization was found to persist for up to 6 weeks at 5°C. In a similar study, the combined effect of irradiation followed by heat on the destruction of *L. monocytogenes* in roast beef and gravy was investigated.[44] An irradiation dose of 0.8 kGy was sufficient to cause heat sensitization. The radiation-induced heat sensitivity persisted for up to 2 weeks at 3°C. This synergy between irradiation and heat, coupled with the persistence of the radiation-induced heat sensitization could be advantageous in irradiated foods such as raw meats, which are cooked before consumption, and in ready meals, which are reheated prior to consumption. The simultaneous application of irradiation and heat can have a significant effect on microbial inactivation, particularly in foods with a high water content.[132] This can be one method of inactivating the resistant spores such as *C. botulinum*, where there is a dramatic drop in D_{10}-values at temperatures near 100°C, but the practical difficulties make this an unlikely commercial option at this time.

Hydrostatic pressure, another physical treatment, during or following irradiation can also increase the inactivation of spores.[138] The D_{10} of *B. pumilus* spores irradiated in potassium phosphate buffer (pH 6.8) under a pressure of 1085 atmospheres (approximately 100 MegaPascals) was 0.32 kGy compared to a D_{10} of 2.7 kGy when the spores were irradiated at atmospheric pressure.

The use of irradiation combined with modified atmosphere packaging (MAP) has been reported by several authors.[41,69] Some meat products are packaged under modified atmospheres, usually with increased levels of CO_2, to increase shelf life. Although MAP can reduce the growth rate of some undesirable microorganisms, including spoilage and pathogenic bacteria, it generally does not kill them. When the atmosphere is removed (the pack is opened), there is an initial lag phase before microorganisms, such as the pseudomonads, begin to multiply again and ultimately spoil the meat. This combination of irradiation and MAP has potential as it could be possible to reduce the numbers of spoilage and pathogenic microorganisms by irradiation and suppress the growth of surviving microorganisms during storage, using MAP, without significantly affecting organoleptic quality.

Packaging of pork chops in a gas atmosphere of 25% CO_2:75% N_2 followed by irradiation at 1.75 kGy was found to significantly reduce the growth of microorganisms. A shelf life of 12 days at 4°C was obtained, compared to 3 days for unirradiated chops packaged in air and 8 days for unirradiated chops packaged in 25% CO_2:75% N_2. In sensory tests, panelists preferred the color and odor of the MAP/irradiated pork.[140] A series of inoculation studies, using a variety of vegetative pathogens, indicated that the combination of 25% CO_2:75% N_2 followed by irradiation to 1.75 kGy, significantly improved the microbiological safety of the pork.[41] Pork is more frequently associated with human botulism than other meats, implying that it is more frequently contaminated with *C. botulinum*. The combined effects of low dose irradiation, modified atmosphere packaging, and storage temperature on the ability of *C. botulinum* type A and B (proteolytic) strains to produce toxin in fresh pork have been investigated.[67] Five strains each of type A and B heat-shocked spores were inoculated onto pork loins at a level of approximately 10^3 spores g^{-1}. After 2 days at 25°C, toxin was detected at all dose levels (0, 0.5, and 1 kGy) and at all initial oxygen levels (0%, 10%, and 20%, in N_2). At 15°C, all samples packaged in 10% and 20% O_2 were toxic after 14 days. At 0% O_2, with an oxygen absorbent, it took 21 and 43 days, respectively, for 0 and 1 kGy samples to be toxic. No toxin was found in any samples stored at 5°C, even after 44 days. It was concluded that the enhancement of toxin production in the presence of oxygen at 15°C was likely the result of respiratory CO_2 production stimulating spore germination.

In a related study[68] with two levels of O_2 and CO_2 (0% and 20% O_2, in N_2) and two radiation doses (0 and 1 kGy), it was observed that 1 kGy delayed toxin production only in samples packaged under 20% CO_2. It took 2 weeks longer to detect toxin in packs with 20% CO_2:80% N_2 than with 20% O_2:80% N_2 and toxin production was faster with 20% O_2:80% N_2 than with 100% N_2. The authors speculated that the slower rate of toxin production in the absence of O_2 was due to lactic acid bacteria outcompeting *C. botulinum* vegetative cells. The fact that toxin production is more rapid in 20% O_2 (similar to the composition of air) and that sensory problems due to oxidative rancidity are reduced in anoxia, suggests that pork could be irradiated successfully and safely in vacuum packages.[9]

The combination of chemical preservatives with irradiation has been investigated by several authors. The addition of sodium chloride to foods can reduce the radiation dose requirement. When *C. botulinum* type A and B spores were inoculated into turkey frankfurters, sodium chloride combined with irradiation (5 and 10 kGy) was more effective at inhibiting toxin production than the combination of irradiation with potassium or magnesium salts.[13] An inoculum level of 450–500 spores g^{-1} with a sodium chloride concentration of 2.5% and storage temperature of 27°C resulted in nonirradiated samples becoming toxic within 4 days. However, similar samples irradiated to 5 kGy were toxic after 40 days, while samples given a 10 kGy treatment were not toxic at 50 days, the maximum incubation time of the experiment. Other salts can be used effectively in combination with radiation. Rowley et al.[109] demonstrated that a combination of 40 μg nitrite g^{-1} and 15 kGy was sufficient to prevent toxin formation in bacon inoculated with 2 spores g^{-1} of *C. botulinum* (10 strains of type A and B) during storage at 27°C for 60 days. The incidence of *C. botulinum* in bacon is normally 10^{-3} to 6.4×10^{-5} cells g^{-1}. The authors considered therefore that a level of 2 spores g^{-1}, as used in their experiments, gave a sufficient safety margin.

4.8 CONSUMER CONCERNS

4.8.1 Mutations

It is well established that irradiation can increase the rate of mutation in living organisms, including bacteria. In theory such mutations could be more pathogenic than parent strains. However, a survey of the scientific literature suggests that this is not the case.[55] Conversely, it has been found that radiation treatment can result in loss of virulence and infectivity. In many cases, irradiated microorganisms exhibit reduced fitness for their environment and become more sensitive to heat, drying, and antimicrobial agents.[24] These mutants are at a disadvantage and do not compete well with nonirradiated organisms that would be encountered in practical situations. Mutants, therefore, usually disappear unnoticed. It should be noted that irradiation is not unique in its ability to increase mutation rates. Thermal processing and some food preservatives can all increase mutation rates in microorganisms, yet there is no evidence that they have caused problems due to increased virulence.[85]

Another concern is that radiation-resistant mutants might develop, particularly as a result of repeated irradiation treatments.[89] It is possible to induce radiation resistance by subjecting bacteria to many cycles of extremely low dose irradiation (<0.1 kGy). In such experiments, survivors from a single irradiation treatment are allowed to reach high numbers and then reirradiated. This process is repeated many times and eventually survivors become more radiation resistant than the original population.[77] It was subsequently shown that salmonellae with this acquired resistance were weakened in other physiological characteristics, even to the point that some were less infective than the parent strain.[73] In practice, food is only irradiated once with a dose suffi-

Next Page

cient to achieve a technological objective, eg, >1 kGy for microbial control, so such circumstances should not occur in practice. Again, radiation is not unique in inducing resistance under specialized conditions. Heat resistance can be induced in salmonellae by repeated cycles of exposure to heat, but this has not caused problems in pasteurization plants.[24]

The possibility that radiation might change the properties of bacteria, particularly pathogens, so that they escape correct identification has been considered.[55] It has been found that the most characteristics remain unchanged after mutation, and they can be identified by the usual methods.

The use of irradiation to produce microbial strains for a particular industrial purpose is well known. For example certain strains of *P. notatum* have been developed that produce increased yield of penicillin.[24] Similarly, selected microbial strains are used in vitamin and amino acid production. In all these cases, the mutants were screened so that only desirable strains were selected, and recovery conditions carefully were chosen so that they could survive. In conclusion, mutants are unpredictable. There is no guarantee that a new pathogenic strain will not arise from a parent microorganism, irradiated or not. However, expert opinion is that such an event is most unlikely.[24]

4.8.2 Methods for Detecting Irradiated Foods

Methods for detecting irradiated foods and quantifying the absorbed dose are desirable. This would allow governments to enforce labeling legislation both for foods produced within their country and for imported products. In turn, this should increase consumers' confidence in their choice to purchase irradiated or nonirradiated food. If irradiated products are chosen, the ability to quantify the dose would ensure that the technical purpose of the treatment has been achieved; for example, that the correct dose was applied to chicken to ensure effective reduction in *Salmonella* and other pathogens.

The ideal detection method should be simple, inexpensive, rapid, reliable, require a relatively small sample size, allow for the detection of a wide range of doses, and not give false positives. In addition, it should have general application to a range of foods, allow the dose to be quantified, and be able to identify irradiated constituents in combination foods.[8] At present, such a perfect universal method does not exist and may not be available for some time in the future. The analytical problem is that most, if not all, chemicals formed as a result of irradiation are not unique, and are naturally occurring or are produced by other treatments such as thermal processing.

The changes in lipids after irradiation has led to the development of gas-liquid chromatographic (GLC) methods for detecting irradiated foods. Although many of the volatile products formed by irradiation are similar to those produced by heating and autoxidation, their distribution patterns vary. This is a promising method for identifying irradiated foods containing lipids such as meat, fish, and eggs. The method does not require specific expertise above that necessary for the routine use of GLC equipment.

Irradiation can result in the formation of free radicals although these are also generated by processes such as heating. Radicals resulting from irradiation give a unique signal when subjected to electron spin resonance (ESR). This technique could be used to quantify the dose in poultry meat by analyzing bone samples, in shrimp by analyzing the shell, and in strawberries by analyzing the achenes. Although the technique is well established, it requires expensive equipment and skilled operators.

Luminescence is another promising detection method. Luminescence is the emission of light when trapped energy is liberated either by the addition of a chemical (chemiluminescence, CL) or by heating (thermoluminescence, TL), when trapped charge carriers are released. Both CL and TL have been used successfully in identifying certain irradiated spices and vegetables.

Other methods being evaluated include inhibition of seed germination as a way of detecting irradiated citrus, the use of electrical impedance to detect irradiated bulbs and tubers, measurement of DNA fragmentation by microelectrophoresis, and the comparison of the aerobic plate count with direct staining, using the direct epifluorescent filter (DEFT) technique for herbs and spices. Detailed information on various detection techniques can be found elsewhere.[7]

4.9 CONCLUDING REMARKS

Treating food by ionizing radiation is an effective means of inactivating spoilage and pathogenic microorganisms and parasites. The safety and effectiveness of food irradiation as a food processing/preservation method have been recognized by the Codex Alimentarius Commission of the FAO/WHO Food Standards program when it adopted the Codex General Standard for Irradiated Foods and its associated Code of Practice in 1983. It is increasingly recognized by national authorities as a method to control foodborne diseases of solid food, especially those of animal origin, in the same manner as thermal pasteurization is recognized for liquid food. Its property as "cold pasteurization" process offers unique advantages for inactivating spoilage and pathogenic microorganisms in frozen food and food intended to be consumed raw or minimally processed, both of plant and animal origin. Similar to other substerilization processes of food, food to be processed by irradiation must adhere strictly to the Code of Good Manufacturing Practices (GMPs) and irradiated food must be handled according to GMPs.

Many national authorities have increasingly demanded that food be processed based on the principles of hazard analysis critical control point (HACCP) to ensure its safety. Unlike commercially pasteurized liquid food, which has thermal pasteurization as its critical endpoint treatment to ensure its safety, other foods in the raw or frozen state have no critical endpoint treatment to ensure safety. The critical control point for the latter type of food is passed on to consumers and those who are involved in food preparation to cook food properly to ensure its safety. Experience of foodborne disease outbreaks in many countries have demonstrated that improper food preparation and cross-contamination during the process of food preparation was largely responsible for these outbreaks. While recognizing the importance of food preparation to ensure food safety, irradiation appears to be the only effective critical control point under the HACCP principle to ensure safety of solid food at the point of sale or for those intended to be consumed raw or undercooked.

With the increasing trade liberalization following the successful conclusion of the GATT Uruguay Round followed by the establishment of the World Trade Organization in 1995, the role of irradiation as a method to ensure hygienic quality of food, especially those of animal origin, is likely to be more prominent and in some cases, eg, spices and other food ingredients, is likely to be used routinely by the food industry. It is therefore most important that every effort be made by governments, the food industry, consumer organizations, and the media to inform the public of the safety and benefits of food irradiation as an effective method to inactivate microorganisms in food.

5.1 INTRODUCTION

Refrigerated storage is now one of the most widely practiced methods of controlling microbial growth in perishable foods. Sales of chilled food products in Europe and North America have increased rapidly in recent years. As a consequence, it is vital that good chill storage procedures are in place to ensure that such foods not only achieve their required shelf lives but are safe for consumption by the end user. While most major food manufacturers and retailers operate a constant and effective cold chain, surveys in the United States (US) have revealed that 20% of domestic and commercial refrigerators operate at temperatures >10°C.[63,138] Because all foodborne pathogens can survive and some can grow at normal refrigeration temperatures (5°–6°C) it is essential, before drawing up legislation governing the refrigerated storage of food products, to understand how microbial growth is affected by low temperatures.

When temperatures are lowered below the optimum for growth of a particular microorganism, lag time and generation time increase and growth rate decreases until, as the temperature approaches the minimum for growth, cell division ceases.[79] At any given temperature, growth rates differ according to the species of organism, and the minimum growth temperature for each organism is different. There can also be considerable strain variation in terms of minimum, maximum, and optimum growth temperatures.

The ability of microorganisms to grow at low temperatures was first demonstrated by Forster in 1887,[37] and subsequently they have been isolated from a diverse range of natural habitats and chill-stored food products.[32,55,91,92,109,120,134] Microbial growth involves an integrated sequence of metabolic steps that are markedly influenced by temperature. The basis of this relationship can be defined mathematically by modifying the equation originally derived by Arrhenius[5] to describe the effects of temperature on chemical reactions:

$$K = Ae^{-E/RT}$$

where K = the velocity constant for a given chemical reaction, R = the gas constant, T = temperature in °K, E = the activation energy, and A = a constant. By substituting growth rate for K and designating E as the temperature characteristic for growth (μ) the equation can be applied to living cells[9]: growth rate = $Ae^{-\mu/RT}$. When a plot of $\log_{10}$ growth rate against 1/°K is made, the slope of the linear portion of the curve equals $-\mu/_{2.303R}$, and from this the temperature characteristic for growth can be determined (Figure 5-1). The linear region of the curve demonstrates the compliance of growth rate with temperature according to the Arrhenius principle. However, the linear region is limited to a restricted temperature range for a given microorganism. Above and below these limits, there is an increasing deviation from linearity until the slope becomes vertical. These deviations from linearity define the temperatures at which growth ceases, and they correspond to the upper and lower limits for growth. Ratkowsky et al.[108] modified the Arrhenius equation and showed that if the square root of the growth rate was plotted against absolute temperature, the relationship was linear with no deviations from linearity between the optimum and lower limits for growth. However, at temperatures approaching the upper limit for growth, the relationship deviated from linearity because of thermal denaturation of cellular proteins. By modifying their original equation Ratkowsky et al.[107] were able to accommodate the deviation from linearity, which they had observed at the upper limit for growth. The revised nonlinear regression model is described by the following equation:

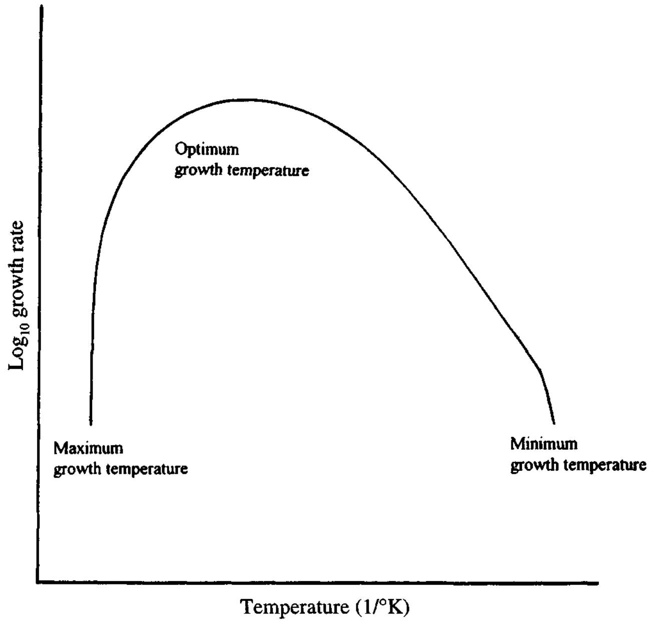

Figure 5-1 Arrhenius Plot Showing the Relationship between Temperature and Growth Rate. *Source:* Copyright © 1989, R.A. Herbert.

$$\sqrt{r} = b(T - T_{min})\{1 - \exp[c(T - T_{max})]\}$$

where r = growth rate, T_{min} and T_{max} are the minimum and maximum temperatures at which the growth rate is zero, b = a regression coefficient of the growth rate constant versus degrees Kelvin for temperatures below the optimum for growth, and c = an equivalent regression coefficient for temperatures above the optimum for growth. This model has been extensively tested and shown to apply to all the bacteria investigated.

Microorganisms have characteristic maximum, minimum, and optimum temperatures for growth, the so-called cardinal temperatures.[122] These have been traditionally used by microbiologists to classify microorganisms into various thermal groups according to their ability to grow at low, intermediate, and high temperatures. Microorganisms capable of growing at low temperatures have been termed *psychrophiles,* those at intermediate temperatures *mesophiles,* and those at high temperatures, *thermophiles.* While the latter two groups can be readily distinguished by their growth temperature optima, it is more difficult to precisely define microorganisms that grow at low temperatures. Consequently, there has been extensive debate on the terminology to be used to define those microorganisms that are specifically adapted to grow at low temperatures (psychrophiles) and those that are merely cold tolerant (psychrotrophs).[65,92,93,115,132] Today, the definition proposed by Morita[94] has gained the most widespread acceptance. He defined psychrophiles as microorganisms that have optimum growth temperatures <15°C, a maximum of ~20°C, and a minimum of 0°C or lower; whereas psychrotrophs, while still capable of growth at low temperatures, have temperature optima >15°C and an upper limit for growth >25°C. Psychrophiles have been less frequently isolated than psychrotrophs and tend to be found, although not exclusively, in permanently cold environments.[57,129,134,136] In contrast, psychrotrophs represent a more diverse range of microorganisms, which are readily isolated from environments subject to fluctuating temperature regimes.[120,138]

5.2 DISTRIBUTION OF PSYCHROPHILIC AND PSYCHROTROPHIC MICROORGANISMS IN NATURAL ENVIRONMENTS

Psychrophily and psychrotrophy, the ability to grow at low temperatures, is a common property of many prokaryotes and eukaryotes including eubacteria, cyanobacteria, yeasts, filamentous fungi, and micro-algae.[57,68,92,93,134,141,142] Within the eubacteria, Gram-negative representatives are predominant. For example, Tanner and Herbert showed that in maritime Antarctic waters, where temperatures never exceed 0°C, approximately 50% of the bacteria isolated could be assigned to the genera *Vibrio*/*Aeromonas*, 25% as *Alcaligenes* species, and the remainder to the genera *Pseudomonas* and *Flavobacterium*.[134] Similarly, Kaneko et al.[76] showed that in the Beaufort Sea isolates, identified as *Flavobacterium* species and *Microcyclus* species, were the dominant species present in the surface waters together with *Vibrio* species and other unidentified Gram-negative bacteria. Gram-negative bacteria belonging to the genera *Pseudomonas* and *Alcaligenes* are also dominant in the soils from the maritime Antarctic.[31] In contrast, in the Antarctic Dry valleys of Southern Victoria Land, the soils are dominated by Gram-positive bacteria identified as *Planococcus* species and *Micrococcus* species.[21] In addition to bacteria, a number of psychrophilic yeasts, including *Candida gelida*,[98] *Candida nivalis*,[97] *Leucosporidium scottii*,[149] and *Cryptococcus vishniacii*[142] have also been isolated from Antarctic soils.

Psychrophilic and psychrotrophic microorganisms are not solely confined to the polar regions but have been isolated from a diverse range of temperate environments.[120,130,154] In addition, they have been isolated from dairy products including raw and pasteurized milk,[36] cream,[32] and butter[71]; chilled stored beef[18,51,131]; and vegetables.[60,125] These data indicate that psychrophilic and psychrotrophic microorganisms are ubiquitous in nature and are present in a diverse range of habitats.

The characteristic features of psychrophiles and psychrotrophs are that they are predominantly Gram-negative, aerobic, asporogenous, rod-shaped bacteria. These have been assigned to the genera *Pseudomonas*, *Flavobacterium*, *Alcaligenes*, and *Vibrio*. It is evident that a number of pathogens can grow and may produce toxins at temperatures of 5°C or below. These include *Aeromonas* species, *Clostridium botulinum*, *Bacillus cereus*, *Listeria monocytogenes*, *Yersinia enterococolitica*, and a number of *Salmonella* species, and this is of particular concern to food microbiologists.

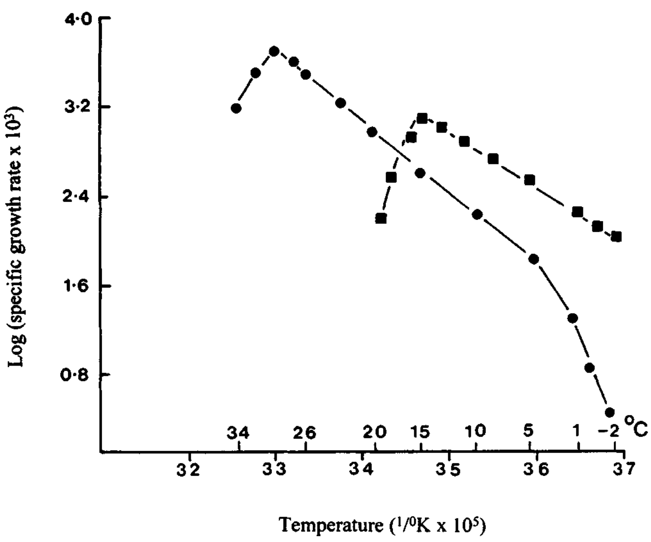

Figure 5-2 Growth Rate and Temperature Relationship. Arrhenius plot showing the relationship between growth rate and temperature for a facultative (●) and an obligate psychrophilic *Pseudomonas* species (■). *Source:* Adapted with permission from W. Harder and H. Veldkamp, Physiology of an Obigately Psychrophilic Marine Pseudomonas Species, *Journal of Applied Bacteriology*, Vol. 31, pp. 12–23, © 1968, Society for Applied Microbiology.

5.3 EFFECT OF TEMPERATURE ON THE GROWTH OF PSYCHROPHILES AND PSYCHROTROPHS

The kinetics of the growth of both psychrophilic and psychrotrophic bacteria have been determined. Data presented in Figure 5-2 show that the difference between these bacteria is in the temperature range over which the Arrhenius curve is linear, rather than the gradient of the linear region of each curve.[52] Thus, the curve for the psychrophilic *Pseudomonas* species does not deviate from linearity until a temperature of –2°C is reached, whereas for the psychrotroph, the slope becomes nonlinear at ~5°C. These data show that psychrophiles have a faster growth rate at low temperatures than psychrotrophs, and this has been confirmed experimentally in competition experiments. Morita and Haight[95] reported that the psychrophile, *Vibrio marinus* MP-1 had a mean generation time of 3.7 hours at 3°C, while Larkin and Stokes[81] claimed that *Bacillus psychrophilus* would grow at –5°C with a doubling time of 6.3 hours. In contrast, psychrotrophic bacteria grow more slowly. For example, *Micrococcus cryophilus* has a mean generation time of 28.2 hours at 0°C, and *Pseudomonas fluorescens* will double its population every 26.41 hours.[58,112] A characteristic feature of psychrophilic microorganisms is their low optimum growth temperature and their inability to tolerate relatively moderate temperatures. Data presented in Table 5-1 show that optimum growth temperatures range from 4°–15°C while maximum growth temperatures, with the exception of *Vibrio*

Table 5-1 Optimum and Maximum Growth Temperatures for a Selected Range of Psychrophiles

Isolate	*Optimal Growth Temperature (°C)*	*Maximum Growth Temperature (°C)*
Vibrio marinus MP-1	15	20
Ant-300 (*Vibrio* species)	7	13
Pseudomonas species	14	19
Vibrio AF-1	15	21

species Ant-300, are in the range 18°–20°C. While growth of microorganisms has been reported at temperatures below 0°C, there is currently no consensus of what temperature constitutes the lower limit for growth. Theoretically, the lowest temperature that might allow growth to occur is ~ –130°C, since below this temperature no "free" water is available.[151] In practice, the lowest temperature at which microbial growth has been unequivocally demonstrated is –12°C for bacteria,[66] although in the literature there are unsubstantiated reports of fungi growing at –20°C and yeasts at –34°C. These finding are consistent with the observation that at temperatures < –10° to –15°C, intracellular water begins to freeze resulting in ionic imbalance, pH shifts, and a concomitant reduction in water activity. These changes, either singly or in combination, exert a toxic effect on the cells that is either lethal or severely impairs metabolic function.[115] Thus, the minimum growth temperature of psychrophiles is set by the temperature at which their cytosol freezes. However, at temperatures above the minimum for growth and where ice is present, growth is also influenced by water activity (a_w). Thus, in part-frozen systems, the a_w is reduced, for example at –5°C the a_w is lowered to ~0.95, while at –10°C the value is ~0.9. Microorganisms, growing under such conditions must therefore be not only cold tolerant but also able to grow at low water activities.

5.4 EFFECTS OF TEMPERATURE ON SOLUTE UPTAKE

From the preceding section, it is evident that psychrophiles form a distinct thermal group because of their ability to grow rapidly at low temperatures. To achieve rapid growth, it is essential that substrate uptake is not the limiting step. A number of workers have proposed that the minimum temperature for growth of psychrotrophic microorganisms is governed by their capacity to transport solute molecules across the cytoplasmic membrane.[38,57,67,94] Support for this hypothesis has come from comparative studies on the respiratory activity of a psychrotrophic *Candida* species and a mesophilic strain of *Candida lipolytica* grown at different temperatures.[9] The psychrotroph was able to respire exogenous glucose at 0°C, whereas the mesophile showed no activity at temperatures <5°C. However, the mesophile was able to respire endogenous substrates at temperatures <5°C, implying that the limiting factor was the ability to transport sugars into the cell at near-zero temperatures. Similar results have also been reported for mesophilic strains of *Candida utilis* and *Arthrobacter* species.[100] While psychrotrophs continue to transport substrates at low temperatures (~0°C), the rates recorded are significantly lower than those measured at higher temperatures, thus confirming that they are cold tolerant rather than cold-adapted organisms. This was demonstrated by Herbert and Bell[57] in their comparative study of glucose and lactose uptake by psychrophilic and psychrotrophic bacteria. These workers showed that sugar uptake in the psychrophilic bacteria was maximal at 0°C and decreased with increasing temperature, whereas the converse was observed with the psychrotrophs. These results are in agreement with those obtained by Fukunaga and Russell.[38] However, not all psychrophilic microorganisms show this pattern of substrate uptake. For example, in *Micrococcus cryophilus,* substrate uptake was, within the limits of experimental error, the same at 0°C and 20°C.[112] Similarly, uptake of L-leucine and 2-deoxyglucose by a psychrophilic Gram-positive bacterium remained unaffected during growth at low temperatures.[152]

It is clearly evident that psychrophiles/psychrotrophs can be distinguished from mesophiles by their ability to transport solutes at temperatures <5°C. Farrell and Rose[34] proposed a number of mechanisms to account for the inability of mesophiles to transport solutes at near-zero temperatures. These include:

1. Solute carrier proteins in the cytoplasmic membrane are less sensitive to low temperature inactivation than those in mesophiles.
2. Solute carrier proteins in mesophilic microorganisms are not abnormally cold labile, but owing to changes in the molecular architecture of the lipid bilayer at low temperatures, they are unable to bind to their respective substrates.

3. At low temperatures, there is insufficient energy available to energize membrane transport systems in mesophiles.

To date, there are no convincing data to show that individual solute transport proteins in mesophiles are abnormally cold sensitive or that ATP availability limits solute uptake. As a result, the majority of studies have focused on determining the effects of low temperatures on the lipid composition of the cytoplasmic membrane and how these changes modify the liquid-crystalline state of the lipid bilayer.

5.5 EFFECTS OF TEMPERATURE ON MEMBRANE STRUCTURE AND FUNCTION

5.5.1 Modification of Membrane Composition

Lipids are a major component of all cell membranes and constitute some 40% to 70% of the total membrane dry weight.[56] As in higher organisms, glycerol phosphatides are the predominant structural lipid class present in bacterial cell membranes and are fatty acid esters of sn-glycerol-3-phosphate. Phosphatidylethanolamine, the most widely distributed phospholipid in bacterial cytoplasmic membranes, is often the dominant component in Gram-negative species. In addition, phosphatidylglycerol and diphosphatidylglycerol (cardiolipin) are commonly found in bacteria, whereas diphosphatidylserine is normally a minor component because it is rapidly decarboxylated to give phosphatidylethanolamine. While phosphatidylinositol and phosphatidylglycerol are important components of eukaryote membrane systems, they are uncommon in bacteria.[46] Equally, bacterial membranes rarely contain sterols such as cholesterol and, if present, the quantities synthesized are insignificant compared with those found in higher organisms. Their absence in prokaryote membrane systems has proved extremely useful when investigating the effects of temperature on gel to liquid-crystalline phase transitions in lipid bilayers.

Within the cell membrane, the phospholipid molecules are arranged in the form of a bilayer with the polar head groups exposed at the extracellular and intracellular surfaces. As a consequence these groups are able to interact with the aqueous environment on the inside and outside of the cell. The hydrophobic fatty acid acyl chains, in contrast, are stacked in a parallel manner perpendicular to the plane of the membrane, with the terminal methyl groups located deep in the interior of the bilayer. Fatty acids in bacterial cells membranes are typically 10 to 20 carbon atoms in length, with C_{16} to C_{18} typically predominating. Bacterial fatty acids may be either straight chain saturated, straight chain unsaturated, branched chain (iso or anteiso), or cyclopropane acids. Long chain polyunsaturated fatty acids, commonly found in eukaryotes, are normally absent in bacteria. Cyclopropane fatty acids are, however, widely distributed among bacteria, while iso and anteiso branched chain acids predominate among the genera *Micrococcus* and *Bacillus.*

Modification of membrane lipid composition in response to lowering of the growth temperature usually involves changes in the hydrophobic acyl chains rather than the polar head groups.[113] This is because the changes in fatty acid composition are more effective in modifying and maintaining membrane fluidity than changes in head group composition. It has been proposed that the physiological significance of these changes in lipid composition is to maintain the lipid bilayer in the fluid liquid-crystalline state.[124] This process, termed *homeoviscous adaptation,* implies that membrane fluidity is maintained at a relatively constant level irrespective of growth temperature. However, in practice, a constant level of membrane fluidity is rarely achieved and under such conditions all that may be required is that there is sufficient membrane fluidity within the lipid bilayer to maintain the liquid-crystalline state. Such a condition might therefore be better described as *homeophasic adaptation.*[87,122]

The most commonly observed response to a lowering of growth temperature is an increase in the proportion of unsaturated fatty acids at the expense of the corresponding saturated acids. This has been elegantly demonstrated in a comparative study of psychrophilic and mesophilic yeasts by Brown and Rose,[20] who showed that at low temperatures the psychrophiles synthesized increased levels of hexadecenoic (16:1) and octadecenoic (18:1) fatty acids compared with their mesophilic counterparts. While similar changes have been recorded in bacteria, the response to low temperatures is considerably more complex and, in addition to changes in the degree of unsaturation of membrane lipids, other modifications may occur, eg, an increase in the proportion of branched chain fatty acids, shortening of the acyl chain length, or a reduction in the proportion of cyclopropane fatty acids.[114,115] The net effect of these changes is to produce membrane lipids with a lowered gel to liquid-crystalline state transition temperature, thereby maintaining membrane function at low temperatures. Data presented in Table 5-2 show that a psychrotrophic strain of *Pseudomonas fluorescens* responded to growth at low temperatures by synthesizing increasing proportions of hexadecenoic and octadecenoic acids while synthesis of the cyclopropane heptadecanoic acid was inhibited at temperatures of 10°C and below. In *Vibrio* AM-1, isolated from the maritime Antarctic, the response to a decrease in growth temperature was to synthesize increased quantities of hexadecenoic (C16:1) and heptadecenoic acid (C17:1) (Table 5-2).[13] A different response was observed in *Vibrio* BM-2, which synthesised increased proportions of short chain fatty acids (C9:1, C12:1, and C14:1) at low temperatures, while the levels of hexadecenoic and heptadecenoic acids showed little change. This response is similar to that recorded by Russell[112] for *M. cryophilus* when grown at low temperatures. The physiological effect of acyl chain shortening is considered to be the same as increasing the proportion of unsaturated fatty acids in the membrane lipids, ie, to maintain a mobile hydrophobic core at low temperatures.

While many microorganisms have been shown to modify their membrane lipid composition in response to a decrease in growth temperature, it is not an absolute requirement; there are several reports in the literature of organisms that show little change in fatty acid composition over a wide temperature range. For example, Hunter and Rose[62] were unable to demonstrate any significant difference in the fatty acid composition of *Saccharomyces cerevisiae* when grown at 15° and 30°C. Similarly, Bhakoo and Herbert[14] were unable to demonstrate significant differences in the lipid composition of psychrotrophic *Pseudomonas* species isolated from maritime Antarctic waters (strain T-6, Table 5-2). In *Pseudomonas* T-6 hexadecenoic (C16:1) and octadecenoic acid (C18:1) were the dominant fatty acids present in the membrane lipids and showed no significant change over the temperature range 0°–20°C (Table 5-3). These data question the absolute need for all prokaryotes to modify their membrane lipid composition as a physiological requirement for growth at low ambient temperatures. Experiments with fatty acid auxotrophs of *E. coli* and *Acholeplasma laidlawii*, in which the membrane lipid composition was varied in a controlled manner to provide a wide range of membrane fluidities, demonstrated that both bacteria continued to grow even though there were major differences in fluidity within the liquid-crytalline phase. Both bacteria could tolerate substantial proportions of gel phase lipid in their cyto-

§Data from Bhakoo and Herbert.[14]

plasmic membranes without loss of membrane function, viz. up to 50% for *E. coli*[70] and 80% to 90% for *A. laidlawii*.[88] These results indicate that there are clear upper and lower limits of membrane fluidity for growth. However, they give no indication of the optimum membrane fluidity. In *E. coli* grown at 37°C, the minimum requirement for unsaturated fatty acids for growth was approximately 20% of the total fatty acid composition.[25] Analysis of the fatty acid profiles of the psychrotrophic pseudomonads and psychrophilic *Vibrio* species show that in all these bacteria the levels of unsaturated fatty acids are considerably in excess of the minimum required for growth. These data support the theory proposed by McElhaney[87] that maintenance of the correct lipid phase is more important than conservation of some absolute value of membrane fluidity.

Equally equivocal are the patterns of change in membrane phospholipids in response to temperature. In a comprehensive study, Bhakoo and Herbert[13,14] investigated the effects of temperature on the membrane phospholipid composition of four psychrophilic *Vibrio* species and four psychrotrophic *Pseudomonas* species. In the psychrophiles, there was a 43% increase in total phospholipid content at 0°C compared with that at 15°C (Table 5-3), accompanied by an increase in cell size.[57] In contrast, in *Pseudomonas* T-6 the phospholipid content remained relatively constant over the temperature range 0°–20°C. Similar results have been reported for *Pseudomonas fluorescens*[42] and other marine psychrotrophic pseudomonads.[19] In *Vibrio* BM-4, diphosphatidylglycerol synthetase and phosphatidylethanolamine decarboxylase were abnormally temperature sensitive and inactivated at 15°C.[12] This finding explains the sharp decline in phosphatidylethanolamine and diphosphatidylglycerol levels recorded at 15°C and the concomitant accumulation of their immediate precursors. In contrast, the same enzymes in the psychrotrophic pseudomonads were thermostable.

5.5.2 Biochemical Basis of Changes in Membrane Fatty Acid Composition at Low Temperatures

While there is an extensive body of data to show the effects of temperature on lipid composition, the mechanisms by which these changes are effected are less well understood. A major difficulty is that these modification processes are regulated in a complex manner at different levels. For example, it is difficult to determine whether temperature directly affects the enzymes involved or whether the effect is an indirect one mediated via membrane fluidity.[115] Clarke[23] summarized the following different levels at which regulation of membrane lipid occurs:

1. regulation of transcription by *de novo* synthesis of desaturase enzymes
2. regulation at the level of enzyme activity by temperature-induced modifications of desaturase enzymes
3. regulation at the level of the membrane by modulating the activity and/or specificity of the glycerophosphateacyltransferase system
4. regulation by control of the relative balance of synthesis and desaturation of fatty acids available to the membranes

In a series of elegant experiments, Fulco[39,40] showed that in *Bacillus megaterium* temperature acted directly on the desaturase by controlling its turnover rate and the transcription of a temperature-sensitive modulator molecule. In this bacterium the desaturase, which only desaturates at the Δ^5 position, is absent in cultures grown at 35°C, whereas at 20°C the enzyme is synthesized. Addition of

chloramphenicol to cell suspensions showed that enzyme synthesis was *de novo*. Similar responses have been reported for *Pseudomonas* E-3 and the Gram-negative bacterium SCRC-2738 when grown at low temperatures.[2,144]

In *Escherichia coli*, the ratio of saturated to unsaturated fatty acids incorporated into membrane lipids is regulated by the relative activities of β-ketoacyl-ACP synthetases, which exist in two forms: synthetase I and synthetase II. In this bacterium, the fatty acid synthetases produce both saturated and unsaturated fatty acids as a result of a branch in the biosynthetic pathway at β-OH-decanoyl-ACP. This C_{10} fatty acid intermediate gives rise to either palmitic (16:0) or palmitoleic acid (16:1 Δ^9 cis). β-ketoacyl-ACP synthetase II is more efficient in elongating palmitoleic acid to cis-vaccenic acid (18:1) and is relatively more temperature sensitive than synthase I. As a consequence, a greater proportion of cis-vaccenic acid is synthesized at low temperatures.[143] Fatty acid composition in *E. coli* is therefore mediated by temperature modulation of preformed enzymes.

The glycerol phosphate acyltransferase system has been proposed to play an important role in controlling the quantity and type of fatty acids acylated into phospholipids.[116] This enzyme exists in an active monomeric and inactive oligomeric form, and it has been postulated that reversible oligomerization is the mechanism whereby the activity of this enzyme system is regulated.[117] A number of studies have shown that the glycerol phosphate acyltransferase system is sensitive to lipid acyl composition, and it has been proposed that this enzyme functions by "sensing" changes in membrane fluidity as a result of temperature shifts.[88] However, the experimental evidence to support this hypothesis is still lacking.

It has been demonstrated that many microorganisms respond to a rapid temperature downshift by aerobic desaturation of preexisting saturated fatty acids.[113] Most workers consider the substrate to be membrane lipid, and this system provides a rapid initial modification of existing membrane lipid in response to sudden temperature changes. The advantage of this system is that it enables rapid modification in fatty acid composition of existing membrane lipid for the minimum expenditure of energy in response to temperature change.

5.6 EFFECT OF TEMPERATURE ON PROTEIN SYNTHESIS AND ENZYME ACTIVITY

Because psychrophiles are able to grow at low temperatures, it is implicit that their enzymes are able to maintain structural integrity and catalytic function at these temperatures. However, in contrast to the extensive literature on mesophilic and thermophilic enzymes, there is a paucity of data on how the intrinsic structure of psychrophilic proteins enables them to function efficiently at low temperatures. Two experimental approaches have been adopted to investigate the mechanisms of thermostability of proteins at different temperatures: (1) determination of the amino acid sequence of the native protein and site-directed mutant forms of the same enzyme but with altered thermostability, and (2) comparative studies of the same enzyme isolated from psychrophilic, mesophilic, and thermophilic microorganisms. Results from these different experimental approaches have yielded essentially the same conclusion, namely that the thermal stability of proteins is an intrinsic property of the peptide chain.[84] Schlatter et al.[118] determined the amino acid sequence of lactate dehydrogenase obtained from *Bacillus psychrosaccharolyticus*. The enzyme from this psychrotrophic bacterium has a significantly lower temperature optimum than the equivalent enzyme isolated from closely related mesophilic and thermophilic *Bacillus* species. It has been postulated that the psychrophilic enzyme should have weaker hydrophobic bonding in the core region and additional hydrophobic bonds at the surface.[158] However, experimental evidence to support this hypothesis is lacking and must await the results from comparative studies in order to identify the specific amino acid substitutions that confer psychrophilic properties on the enzyme. The search for key amino acid substitutions is complicated by the fact that free energy of the native and denatured state of an enzyme is small.[85] As a consequence only a few amino acid residues may be involved.

Recently, Ochiai et al.[101] demonstrated that the psychrophilic bacterium, *Vibrio* ABE-1 synthesizes two isocitrate dehydrogenase isoenzymes that exhibit different thermal characteristics. The monomeric form, isoenzyme I, appears to be cold adapted and functions at 0°C but is denatured at temperatures >15°C. In contrast, the dimeric form, isoenzyme II, is more thermostable but exhibits decreased activity at low temperatures. The two isoenzymes have a similar amino acid composition although there are slight differences in the content of nonpolar and hydroxyl amino acids.[69] Whether these differences in amino acid composition are sufficient to account for the observed differences in thermostability and activity has yet to be demonstrated.

A further feature of microbial growth at low temperatures is that protein synthesis must also function at such temperatures. Several comparative studies of *in vitro* protein synthesis in mesophiles and psychrophiles have demonstrated that in the latter organisms the miscoding rate at 0°C was lower.[80] This study indicated that the ability to synthesize proteins efficiently at 0°C was an intrinsic property of the ribosomes and not of soluble components in the cell-free extract. Szer[133] isolated a ribosomal protein(s) from the psychrophilic bacterium, *Pseudomonas* strain 412, which confers the ability to translate specific mRNAs at 0°C. When this protein(s) was removed by washing, the ribosomes lost the capacity to synthesise proteins at low temperature. Araki[4] compared rates of protein synthesis in cell-free extracts prepared from *Vibrio* ANT-300 at 0° and 13°C and showed that the process was regulated by soluble factors. He identified 24 soluble proteins whose concentrations changed with temperature but no functions have been ascribed to any of them.

In natural environments where microorganisms are commonly subject to rapid changes in temperature, it is perhaps not surprising that they have evolved protection mechanisms. *E. coli*, for example, synthesizes cold-shock proteins in response to a temperature downshift.[73] Several of these cold-shock proteins have been identified and appear to function mainly in translation, although one major protein (CS 7.4) has been proposed to function, due to its small size, as an antifreeze protein.[73] The psychrotrophic yeast, *Trichosporon pullulans* synthesizes up to 26 different cold-shock proteins in response to a temperature downshift.[74] These data indicate that induction of cold-shock proteins enables microorganisms to withstand and survive rapid changes in growth temperature and must be taken into consideration when determining protocols for the refrigerated storage of food products.

5.7 GROWTH AND SURVIVAL OF FOOD-ASSOCIATED MICROORGANISMS AT LOW TEMPERATURES

5.7.1 Growth at Low Temperatures

Data presented in Table 5-4 show the minimum, maximum, and optimum temperatures for the growth of foodborne pathogens. It is evident from

Notes: T_{min} minimum growth temperature.
T_{opt} optimum growth temperature.
T_{max} maximum growth temperature.

*Nonproteolytic *C. botulinum* also forms toxin at low temperatures. See Chapter 41 for additional details.

†For *E. coli* 0157:H7, the range is slightly more limited, minimum growth temperature being 8°C and maximum 42°–44°C.

‡These values apply to *S. sonnei*. The growth range for *S. flexneri* is more restricted, ie, from 10°–44°C.

§For enterotoxin production, the range is 10°–46°C and the optimum is 40°–45°C.[137]

these data that a number of pathogens can not only grow but also may produce toxin(s) at temperatures of 5°C or below. Consequently, growth can take place under commercial and domestic refrigeration conditions by organisms such as *Aeromonas* species, psychrotrophic *Bacillus cereus*, nonproteolytic *Clostridium botulinum, Listeria monocytogenes,* and *Yersinia enterocolitica*. Some strains of salmonellae, such as *S. bredeny, S. virchow,* and *S. typhimurium* can grow at 5°–6°C, and *S. agona, S. senftenberg,* and *S. hadar* grow at temperatures just above 6°C.[3] While growth at such temperatures may be relatively slow, the potential exists for unacceptable multiplication to occur, given the commercial requirement for long shelf lives to allow for storage at the factory prior to distribution, the distribution process itself, subsequent display in shops and supermarkets, and finally, customer storage prior to consumption.

It is evident from the data presented in Table 5-5 that while the growth of pathogens such as nonproteolytic *Clostridium botulinum* is very slow in nutrient medium at 4°C, a relatively modest temperature increase to 8°C leads to an almost five-fold increase in growth rate. Similarly, psychrotrophic *Bacillus cereus* grows slowly at 5°C but at 7°C the growth rate is almost double. These data demonstrate how a slight increase in temperature (2°–4°C) can not only result in the rapid growth of pathogens but also can create the potential for toxin produc-

tion. Of particular concern to food microbiologists is the fact that refrigeration at temperatures above 3°C cannot be regarded as an absolute safeguard against growth of and toxin production by nonproteolytic *Clostridium botulinum.*[49] Data presented in Table 5-6 show that the growth of pathogens in a diverse range of food products can be rapid at currently permitted refrigeration temperatures (5°–8°C). Growth of food spoilage microorganisms as opposed to pathogens can be even more rapid at these temperatures (Table 5-7). Thus, *Pseudomonas* species growing on meat slices stored at 2°C have mean generation times of 7.6 to 8.2 hours. Similarly, *Brochothrix thermosphacta* growing on bologna sausage stored at 2°C has a generation time of 8.2 hours. Data presented in Table 5-7 illustrate how a relatively modest increase in storage temperature from 2° to 5°C can lead to a significant increase in growth rate of fluorescent pseudomonads with a concomitant reduction in shelf life of the food product. These data graphically demonstrate the growth potential of psychrotrophic and psychrophilic spoilage microor-

ganisms at temperatures that have, until relatively recently, been considered adequate for the refrigerated storage of perishable food products.

5.7.2 Survival of Pathogens at Low Temperatures

It is paradoxical that while refrigeration prolongs the shelf life of perishable foods and prevents the growth of some organisms, it also promotes the survival of foodborne pathogens unable to grow at low temperatures (Table 5-8). For example, the survival of verocytotoxigenic *Escherichia coli* in acidic environments such as apple juice[88] and mayonnaise[53,106,150,156] is appreciably longer at 5°–7°C than at 25°C.

It has been suggested that virulence of pathogenic bacteria can be influenced by the temperature of growth, but the relevant evidence is conflicting. Growth at low temperature was reported to increase virulence of *L. monocytogenes* when assessed by intravenous injection into animals, but not when the

bacteria were administered intragastrically.[26] However, in a later study, growth at low temperature showed no effect on virulence when the organisms were administered by either route.[96]

In some strains of *Y. enterocolitica*, growth at low temperature and suboptimal pH has been reported to increase loss of the virulence plasmid.[16] No change in the fatty acid composition of the cell membrane resulted from growth at low temperature, so this factor was not responsible for the increase in loss of the virulence plasmid.

5.7.3 Factors Influencing Growth and Survival at Low Temperatures

Minimum growth temperatures for microorganisms are influenced by many factors and are lowest when other growth-influencing factors are optimal. Thus, the data presented in Table 5-4 regarding minimum, maximum, and optimum temperatures assume optimal conditions for growth, ie, the substrate was microbiological medium, the pH value was close to 7.0, there was no added humectant to reduce the water activity, and no preservatives present.

Comparison of generation times in Table 5-5 with those of relevant organisms in Table 5-9 shows that the further the environmental conditions deviate from the optimum for a given organism, the greater the corresponding decrease in growth rate. Some bacteria can be highly resistant to specific environmental conditions. For example, the growth rates of *Staphylococcus aureus* and psychrotrophic *Bacillus cereus* are relatively unaffected, even at temperatures near the minimum for growth when 4.0% to 5.0% (w/v) NaCl is present in the growth medium. Thus, the generation time of *S. aureus* when grown in media at 10°C, pH 6.5, and 0.5% (w/v) NaCl is 12 hours, while the addition of 4.5% (w/v) NaCl under the same growth conditions increases the generation time to 14.6 hours. In contrast, the generation time of

Y. enterocolitica is increased from 9 hours at 5°C, under optimum conditions of pH and NaCl, to 17 hours when 4.5% (w/v) NaCl is included in the medium.

Data presented in Table 5-10 demonstrate the effect on growth of foodborne pathogens of inclusion of carbon dioxide in the headspace of polystyrene trays containing filter pads saturated with medium containing foodborne pathogens, to simulate conditions in modified atmosphere packaged (MAP) foods. Calculation of the "inhibition index" (by dividing the generation time in the absence of CO_2 by that at a particular CO_2 concentration) shows that the growth rate of *E. coli* O157:H7 was little affected by concentrations of CO_2 up to and including 40% (w/v) at 10°C. At a concentration of 60% (w/v) CO_2 at 10°C, the generation time was reduced by one-third and 80% (w/v) CO_2 in the headspace prevented growth. However, at 15°C the generation time of *E. coli* O157:H7 was unaffected by even 80% (w/v) CO_2 in the headspace. *Y. enterocolitica* appears somewhat more inhibited by CO_2 in the environment than *E. coli* O157:H7. Gram-positive organisms such as *S. aureus* and *B. cereus* (mesophilic strains) appear to be more sensitive than Gram-negative fermentative organisms to CO_2, and this sensitivity is enhanced at temperatures near the minimum for growth.

This relationship between temperature and CO_2 concentration is significant in the ecology of MAP

foods, because the Gram-negative spoilage microflora is inhibited by CO_2, Gram-negative microaerophilic pathogens may be able to grow relatively unchecked, eg, for fresh meat the normal MAP contains 20% to 30% (w/v) CO_2, with the balance of oxygen for color maintenance. This concentration of CO_2 fails to inhibit growth of *E. coli* O157:H7 at 10°C, and also possibly salmonellae, while growth of *Y. enterocolitica* would be only slightly inhibited. It would therefore seem a reasonable hypothesis that modified gas atmospheres may effectively select for Gram-negative microaerophiles, several of which are foodborne pathogens.[59] This emphasizes the requirement for assiduous temperature control of MAP foods by manufacturers, distributors, and retailers of food and also by consumers.

Data presented in Table 5-11 show the effect of another common preservative, sodium nitrite ($NaNO_2$), on the generation times of salmonellae and *L. monocytogenes*. Systematically increasing $NaNO_2$ concentrations reduced the growth rate of *L. monocytogenes* at 10° and 20°C when conditions of pH and NaCl were slightly suboptimal (pH 6.0, NaCl concentration 4.0% w/v). Comparison of the inhibition indices shows that even 50 mg L^{-1} $NaNO_2$ has a noticeable effect on the growth rate, particularly at 10°C. At 20°C, under the same conditions of NaCl and pH value, the degree of inhibition caused by systematically increasing concentrations of $NaNO_2$ was less evident. Thus, good temperature control is essential for foods that contain $NaNO_2$ as a a preservative, including cured meats and particularly mild-cured products such as frankfurters and some types of bacon and ham.

Under optimal conditions of NaCl and pH value, the growth rate of salmonellae at 10°C was not noticeably affected by 50 mg L^{-1} of $NaNO_2$ (inhibition index equal to 1.0; Table 5-11), but 100 mg L^{-1} of $NaNO_2$ was noticeably inhibitory. However, little additional reduction in growth rate was achieved by further increasing the concentration of $NaNO_2$.

5.8 CONCLUDING REMARKS

The requirement for good and consistent refrigeration of perishable foods throughout the various stages of the chill chain, from manufacture, distribution, and retail to consumer use is demonstrated by the information contained in this chapter. The data suggest that even relatively small increases in temperature can cause a significant increase in growth rate, particularly among spoilage organisms and so-called low temperature pathogens, eg, *L. monocytogenes*, *Y. enterocolitica*, psychrotolerant *B. cereus*, and nonproteolytic *Cl. botulinum*. Furthermore, foodborne pathogens not normally regarded as able to grow at refrigeration temperatures, including salmonellae and *E. coli* O157:H7, are able to multiply, albeit slowly, at a temperature of 8°C. The present-day requirement for long shelf lives for chilled foods could

mean that foodborne pathogens may multiply significantly during long storage of a product at temperatures greater than about 6°C.[11,47,126,153]

Given the above concerns, it is therefore perhaps surprising that current refrigerated storage legislation is not more stringent. Regulations in the US state that refrigerated foods should be maintained at 7.2°C or below as appropriate for the food involved.[24] In the UK, the Food Safety (Temperature Control) Regulations introduced in England and Wales in 1995 stipulate that the maximum temperature permitted for storage of chilled foods is 8°C.[128] This is also the maximum temperature permitted in Sweden, while in Denmark, chilled meat and poultry products must be stored at temperatures of 5°C or less, with a maximum of 2°C for "special" meat and poultry products, eg, those that are modified atmosphere packaged. Some countries have resisted introducing legislation on temperatures on the grounds that it is not possible in practice to maintain them, but instead issue guidelines of an advisory nature.[17] With regard to the data presented in this chapter and our increased understanding of microbial growth at low temperatures, it would appear apposite to reevaluate current refrigeration practices and establish internationally agreed upon standards for the chill preservation of perishable foods.

6 Freezing

Barbara M. Lund

CHAPTER CONTENTS

6.1 Introduction
6.2 The production of frozen food
6.3 Physical changes during freezing
6.4 The effect of freezing on microorganisms
  6.4.1 General comments
  6.4.2 Mechanism of the effect of freezing
  6.4.3 Factors that affect the survival of microorganisms during freezing and thawing
6.5 Examples of the effect of freezing on microorganisms associated with foods
  6.5.1 Bacterial spores
  6.5.2 Gram-positive, vegetative bacteria
  6.5.3 Gram-negative bacteria
  6.5.4 Yeasts and molds
  6.5.5 Viruses
  6.5.6 Protozoa
  6.5.7 Parasites
6.6 The microbial flora of frozen foods
6.7 Outbreaks of disease associated with frozen foods
6.8 Microbiological spoilage of frozen foods
6.9 Concluding remarks
References

6.1 INTRODUCTION

The commercial production of frozen food probably started with ices and ice cream. A Florentine chef was said to have produced ices of different flavors for each day of the celebration of the wedding of Catherine de Medici to the French dauphin in 1534, and it is reported that by 1576 there were 250 master ice makers in Paris.[111] An anonymous manuscript on *L'art de Faire des Glaces* (The Art of Preparing Ice Cream) was written in about 1700, and a treatise on *The Art of Making Frozen Desserts* appeared in Paris in 1768.[67] In the United States (US) in 1865, there are records of the freezing of fish by placing them in pans surrounded by ice and salt.[37] In about 1880, refrigeration machines began to be used to freeze fish, and by 1900 fish freezing had become an important industry. The first reported successful shipment of frozen beef in the US was in 1867. In 1878, the first cargo of frozen meat was transported successfully from Australia to England. Freezing of poultry and fish began at about the same time. Freezing of shellfish and eggs developed later, that of small fruit and berries began in about 1905. The birth of the modern frozen food industry is regarded as dating from 1928, with developments in freezing technology by Clarence Birdseye[83] and in 1929 Birdseye frozen foods were placed on the retail market. Experimental work on freezing of vegetables was recorded in 1917; in 1929 it was recognized that in order to produce frozen vegetables of good quality it was necessary to heat the vegetables briefly before freezing in order to inactivate enzymes that could cause deterioration during frozen storage. This resulted in successful processes, and freezing of vegetables became commercially important in 1937. After 1945, satisfactory methods were developed for the concentration of citrus juices, which resulted in commercial production of frozen citrus juices. In addition to fresh foods, the production of frozen cooked and prepared foods has become a major part of the frozen food industry.

By the mid-1980s, frozen food accounted for approximately 40% of the food consumed in the US

Acknowledgment: The author is grateful to **Dr. Roger Parker,** Institute of Food Research, Norwich, UK, and **Dr. Steve James,** University of Bristol, UK, for constructive comments during the writing of this chapter.

whereas in Europe the percentage ranged from 10% to 25%.[95] In 1996, retail sales of frozen foods in the United Kingdom (UK) were valued at £4.6 billion, and the worldwide frozen food market was valued at £51.6 billion.[42]

In the UK in 1996 the percentage by value of retail sales of different frozen foods was estimated as follows: meat and poultry, 24%; fish, 14%; ice cream, 12%; meat products, 11%; frozen potatoes, 8%; vegetables, 8%; desserts, 7%; meat ready meals, 7%; pizzas, 6%; vegetarian, 3%.[42]

Foods are usually subjected commercially to temperatures of –10°C or colder for one of the following reasons: (1) to preserve the quality and wholesomeness, (2) to create a special structure and consistency, eg, ice cream, frozen yogurt, or (3) to carry out certain production processes. Quick-frozen foods are defined as foods "that have undergone a freezing process known as quick-freezing whereby the zone of maximum crystallization is crossed as rapidly as possible depending on the type of product"[102] and that are maintained at –18°C or colder with a minimum of fluctuations. Other frozen foods such as butter stored in bulk and large cuts of meat or poultry are maintained at –12°C or lower. Ice cream is usually stored at lower temperatures than other frozen foods. According to European legislation, after freezing and temperature stabilization, quick-frozen foods should be kept at temperatures of –18°C or lower except during transport and local distribution, when they may be exposed for brief periods to temperatures not higher than –15°C.[22,23,24,85,102,103] During long-term storage, frozen foods should ideally be kept in primary cold stores in which the air temperature is between –20° and –28°C, and secondary cold stores should be designed to give similar air temperatures.[56,85] It is recommended that frozen fish be stored at –30°C or below in order to maintain high quality.[97] During retail display, it is good practice to keep quick-frozen foods at a temperature of –18°C, as far as possible, but not warmer than –12°C.[22,102] These regulations and recommendations do not apply to products that are not labeled "quick frozen" nor to ice cream or any other edible ice. It is recommended that main factory cold stores for ice cream be well below –18°C,[53] eg, below –30°C,[67] and that the temperature for delivery should not exceed –18°C.

Refrigerators and home freezers in several countries use the International Standards Organization (ISO) system of star marking to designate the temperature of the frozen food compartment. One star denotes a test temperature of –6°C, at which most frozen foods can be stored for up to 1 week.[56] Two stars denote a test temperature of –12°C at which most frozen foods can be stored for up to 1 month, and three stars denote a test temperature of –18°C at which most frozen foods can be stored for up to 3 months. There are few data on the practical storage life of frozen foods but approximate information is shown in Table 6-1.

In general, frozen foods have a good record of safety and quality. The minimum temperature for growth of most bacteria that cause spoilage of meat and other foods is, for practical purposes, probably in the range of –2° to –3°C and that for molds is probably about –8°C; growth at these temperatures is very slow (Section 6.5). Many microorganisms, however, can survive well in frozen foods, and several large outbreaks of disease, as well as sporadic cases, have resulted from the consumption of ice cream or of previously frozen food. After thawing, surviving microorganisms can multiply rapidly in these foods, depending on the temperature, and this can result in safety and spoilage problems. It is clear that strict control of raw materials and control of hygiene by Good Manufacturing Practice (GMP) are required during production in order to ensure the safety as well as the quality of these foods.

6.2 THE PRODUCTION OF FROZEN FOOD

The treatment of food before freezing determines the quality after freezing; the treatments that are needed to obtain the required quality are described in detail elsewhere.[56,64,90,97] In addition to affecting the sensory quality of foods, these treatments influence the microbiology of the frozen food. Before freezing,

Table 6-1 Approximate Storage Life of Groups of Foods at –18°C and –24°C

Product	*Practical Storage Life (months) at –18°C*	*Practical Storage Life (months) at –24°C*
Fruits	18–24	>24
Vegetables	6–24	15–>24
Meats and poultry	10–24	15–>24
Seafood	5–9	9–>12

beef and lamb carcasses should be stored long enough for rigor mortis to occur, when the pH will have fallen to 6.0 or lower. If prerigor muscle is cooled to below 10°C, the muscle contracts because the sarcoplasmic reticulum can no longer bind calcium ions efficiently, a phenomenon called *cold shortening.* This can be prevented by allowing a period of time during which the metabolism of muscle glycogen to lactic acid results in a fall in pH to below pH 6, or by electrical stimulation of the meat. Before freezing it is usually desirable to bleed fish.[97] The majority of vegetables are blanched before freezing.[6] This is mainly in order to inactivate peroxidase, catalase, and lipoxygenase enzymes, which could cause deterioration of flavor and texture during long-term frozen storage. Blanching is done by passage of the vegetables through steam or hot water, usually between 75°C and 95°C for 1 to 10 minutes depending on the size of the vegetable pieces. Vegetables such as bell peppers, cucumbers, leeks, herbs, Jerusalem artichokes, onions, swedes, and turnips (and possibly carrots) will retain high quality without blanching provided that they are maintained at temperatures not warmer than –18°C.

Freezing of ice cream is not merely a means of preservation but is part of the design of the product. Production is described in detail elsewhere[67,91] and a Code of Practice for Hygienic production has been published in the UK.[53] The process for production of hard ice cream is outlined in Figure 6-1. Ice cream is made from a liquid mix that contains milk, cream, water, milk-solids-not-fat, milk fat or other fat, sugars, emulsifying and stabilizing agents, flavor, and color. Following a 1947 outbreak of typhoid fever in Wales, caused by contaminated ice cream, regulations were introduced in the UK requiring heat treatment of ice cream mix. The present UK regulations require that ice cream mixture must not be kept for longer than one hour at a temperature that exceeds 7.2°C before being pasteurized or sterilized. The conditions for pasteurization of ice cream mix in the UK are heat treatment (1) at not less than 65.6°C for at least 30 minutes, (2) at not less than 71.1°C for at least 10 minutes, or (3) at not less than 79.4°C for at least 15 seconds.[104] Slightly greater heat treatments are recommended in the US.[67] Sterilized ice cream must be prepared by heating the mixture to a temperature of not less than 148.9°C for at least 2 seconds. In each case the mix must then be cooled to a temperature of not more than 7.2°C within 1.5 hours of being heated (or in the US, cooled to <5°C) and must be kept at such temperature until the freezing process is begun. Regulations differ slightly in different countries.

After heat treatment, the ice cream mix is homogenized to reduce the size of fat globules, cooled, and stored for up to 24 hours at a temperature of about 3°C. It is then frozen by lowering the temperature rapidly to about –5° to –7°C with agitation and simultaneously air is incorporated. When the ice cream emerges from the freezer, it is either dispensed for sale as "soft-serve" ice cream or packaged in bulk or small packs, hardened at low temperature, eg, –20° to –40°C, and sold as hard ice cream.

Equipment and methods used for the freezing of foods are summarized in Table 6-2 and factors that influence the choice of methods are outlined by Persson and Londahl.[83]

During the freezing of a food any particular location in the food passes through three stages of temperature change: (1) prefreezing, (2) freezing, and (3) reduction to the storage temperature.[83] The *prefreezing stage* starts when the food is subjected to the freezing process and lasts until the beginning of ice formation. The *freezing stage* is that in which the temperature at the specific location remains almost constant because the heat extracted is causing the main part of the water to change to ice. The initial freezing point depends on the composition of the food and is below 0°C; in the case of a highly salted product, such as bacon, it can be below –7°C. The *stage of reduction to storage temperature* is the period during which the temperature is reduced from that maintained during freezing to the required storage temperature. The *freezing time* is defined as the time from the start of the prefreezing stage until the food has reached the final temperature.[56] The *freezing rate*, measured in °C h^{-1}, is the difference between the initial and final temperatures divided by the freezing time. It can be assessed by the speed of movement of the ice front (in cm h^{-1}) through a product; this speed is faster near the surface of the product than near the center. The freezing process can be regarded as complete when the equilibrium temperature has reached the intended storage temperature (–12°C or lower for frozen foods in general; –18°C for quick-frozen foods). The most rapid rate of freezing reached is probably equivalent to a rate of fall in temperature of about 100°–200°C min^{-1} for small particles, eg, peas, and at the surface of other foods, whereas in many cases the rate of fall in temperature will be much slower than this.

Table 6-2 Equipment and Methods Used for Commercial Freezing of Foods

Type of Freezer	*Comments*
Contact freezers	
Plate freezers	Product is pressed between hollow metal plates through which refrigerant is circulated. Used for whole, gutted fish; packaged fish fillets; blocks of fish; and packaged meat products.
Contact belt freezers	Product moves on a belt with refrigerant circulated on the other side of the belt. Can freeze and form product into pellets. Used for chopped spinach purees, fruit pulps, egg yolk, sauces, and soups.
Drum and rotary freezers	Used for pastes, eg, chopped spinach paste; thick liquids; and flat, thin items such as fish.
Air blast freezers	
Blast room	Cold storage room with extra refrigeration capacity. Used for bulk products, eg, butter, beef quarters, and fish.
Tunnel freezer	Loading may be manual or mechanized. Used for most types of food, particularly meat carcasses and 20–30 kg cartons of meat.
Belt freezers	Belts may be multitier or spiral. Used for meat patties, fish fillets, chicken portions, vegetable products, and packaged products such as ready meals.
Fluidized bed freezers	Particles are frozen and conveyed by an upward stream of cold air. Used for sliced or diced vegetables, fruits, meat products, and cooked shrimps.
Cryogenic freezers	
Liquid nitrogen freezers (–196°C at 1 bar)	Liquid nitrogen evaporates to gas at –196°C. The liquid nitrogen is sprayed into the freezer and moves counter-current to the product. Used for meat cuts, fish fillets, shrimps, fruit berries, pies, and pastries.
Liquid carbon dioxide freezers (–78.5°C)	Solid CO_2 sublimes to vapor at –78.5°C. Liquid CO_2 under pressure is sprayed into the freezer and forms a snow, which then sublimes. Used for the same products as liquid nitrogen.
Combination methods	The product is surface frozen in liquid N_2, then passed to spiral belt freezer or fluidized bed freezer for complete freezing.
Form freezing	Liquids or semi-liquids are frozen into pellets. Liquid N_2 is sprayed into product to prefreeze. The frozen product is subjected to high pressure to form pellets, then freezing is completed.

6.3 PHYSICAL CHANGES DURING FREEZING

In addition to the formation of ice, the physical changes in foods during freezing include changes in concentration of solutes and in water activity, which affect the survival of microorganisms. Some of the principles underlying these changes can best be understood in relation to simple aqueous suspensions of microorganisms, but more complex changes may occur in the heterogeneous environment in foods. At 0°C the vapor pressure of pure water and of ice are the same. Low concentrations of solutes reduce the vapor pressure of an aqueous solution as is expressed by Raoult's law:

$$(p_0-p)/p_0 = n_1/(n_1 + n_2)$$

where p_0 is the vapor pressure of pure solvent, p is the vapor pressure of the solution, n_1 is the number of moles of the solute, and n_2 is the number of moles of the solvent. The number of gram molecular weights of water in one kilogram, n_2, = 55.49. The above equation indicates the depression of water activity $(1-a_w)$.

For a one molal aqueous solution

$$n_1/(n_1 + n_2) = 1/56.49 = 0.0177,$$

therefore, for a one molal solution $(p_0-p)/p_0 = 0.0177$, ie, the vapor pressure of a one molal ideal solution will be 1.77% lower than that of the pure solvent, and the solution will be in water vapor pressure equilibrium with a relative humidity of 98.23%; this would be expressed as a water activity (a_w) of 0.9823.[69]

In a one molal ideal solution, the freezing point is lowered by 1.86 K (=1.86°C), ie, the molal depression constant K_f for water, is 1.86 K (= 1.86°C).[10,74] This applies only to simple ideal solutions at low concentrations. For concentrated ionic solutes, the relationship between molality and vapor pressure and between molality and freezing point is more complicated (Chapter 7).

In the case of most foods, freezing begins between −1° and −3°C.[10,54] During cooling below this temperature either supercooling occurs, in the absence of nucleation, or ice crystals begin to form. The formation of ice crystals results in concentration of solute in the remaining solution and a consequent reduction in freezing point of that solution. At each temperature, a certain amount of ice is in equilibrium with a certain concentration of unfrozen solution. The vapor pressure of ice is, therefore, equal to the vapor pressure of the unfrozen solution. The a_w of this unfrozen solution and of the food itself is, therefore, given by the ratio of the vapor pressure of ice to that of water at the temperature concerned.[94] At −5°, −10°, and −15°C, the corresponding values of a_w are 0.9526, 0.9074, and 0.8642, respectively; the a_w in frozen foods can only be controlled by changing the temperature. The relationship between the a_w and temperature for mixtures of ice and aqueous solutions is shown in Figure 6-2.

Eventually all the water that can be crystallized as ice freezes, leaving the solute(s) and its water of hydration, ie, the solution is saturated with respect to the solute. In suitable conditions, further reduction of temperature results in the solidification of the remaining solution. The lowest temperature at which the solution remains liquid is called the eutectic temperature.

If the eutectic temperature is fairly high, eg, −4°C in the case of lactose, conditions will be relatively favorable for formation of a eutectic mixture. If the eutectic temperature is well below the initial freez-

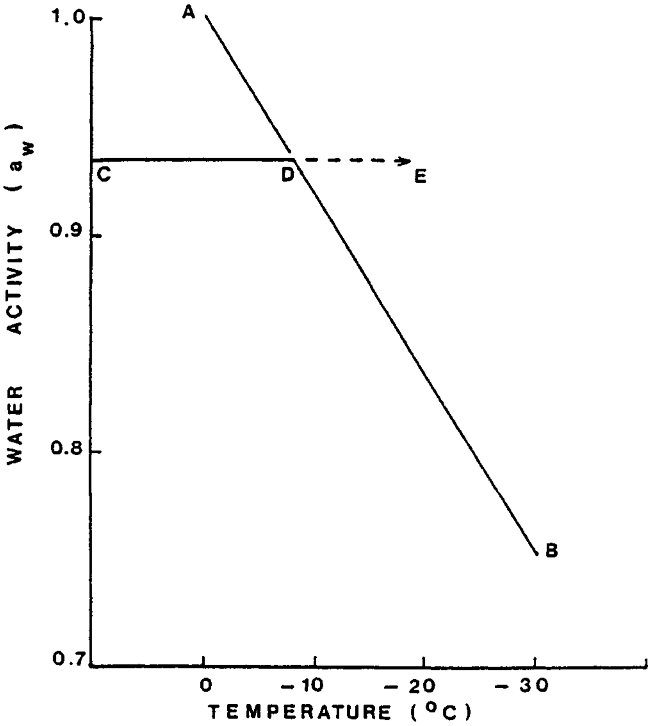

Figure 6-2 The Relationship between Temperature and Water Activity in Partially Frozen Ice/Water Mixtures.[26] The line AB refers to ice and water mixtures. The effect of reduction of temperature on the a_w of a high-solute liquid is shown by line CDB where the freezing point is depressed to D, or alternatively if supercooling occurs the solution remains liquid to temperature E. *Source:* Copyright © 1985, R. Davies.

ing point of the food sample, as in the case of the majority of foods, the unfrozen solution may be very viscous at that temperature, and this viscosity may so reduce the movement of molecules as to prevent the formation of a eutectic mixture. In this case, the unfrozen solution remains in a metastable, supersaturated state, which is probably the situation in most frozen foods.[41] During further cooling this supersaturated, unfrozen phase may either (1) persist as a supersaturated, viscous liquid or (2) be transformed into a glass. This is illustrated for a simple system in Figure 6-3.

In frozen foods that contain a supersaturated, viscous liquid (case 1), physical and chemical changes that are commercially significant can occur during storage, whereas frozen foods where a glassy state occurs (case 2), the rates of physical and chemical change are much lower, thus reducing deterioration during storage. Glass transition temperatures, Tg^1 values, for some food components and foods are shown in Tables 6-3 and 6-4.

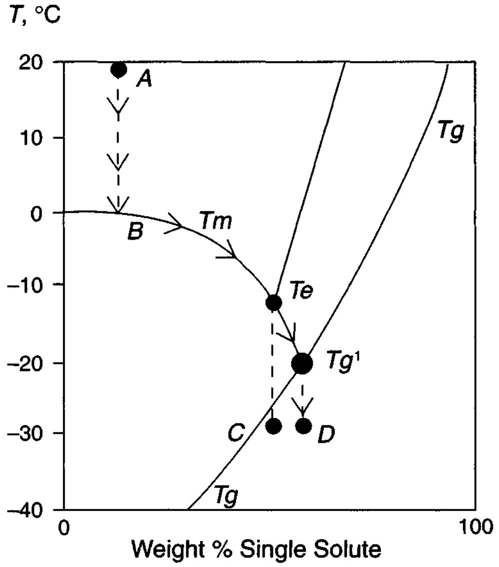

Figure 6-3 Simplified Temperature–Composition State Diagram for an Aqueous Binary System. *Tm* = melting (freezing) temperature; *Te* = eutectic temperature; *Tg* = glass transition temperature; Tg^1 = subzero *Tg* of the maximally freeze-concentrated amorphous solute/unfrozen matrix surrounding the ice crystals in a frozen solution. If a eutectic forms the composition will be unchanged by further cooling (*Te–C*). Further cooling from Tg^1 will not change the composition (Tg^1–*D*). *Source:* Reprinted with permission from O. Fennema, Frozen Foods: Challenge for the Future, *Food Australia,* Vol. 45, pp. 374–381, © 1993, Australia Institute of Food Science & Technology.

Table 6-3 Glass Transition Temperatures (Tg^1) and Molecular Weights of Food Components

Solute	*Molecular Weight (daltons)*	*Glass Transition Temperature* Tg^1 *(°C)*
Glycerol	92.1	−65
Xylitol	152.1	−46.5
Glucose	180.2	−43
Sucrose	342.3	−32
Maltotriose	504.5	−23.5
Maltoheptaose	1153.0	−13.5
Gelatin	30,000–300,000	−9.5 to −12.5
Waxy maize	$>10^6$	−4

The Tg^1 values for vegetables are within the range of storage temperatures for frozen foods, while the Tg^1 values for fruits are rather lower. *Tg* values for meat are likely to be in the range −9.5° to −12.5°C.[41] Rates of physical and chemical change in these frozen foods are likely to be much lower below than above these temperatures.

Other changes that can occur during freezing of foods include change in pH, ranging from 0.3–2.0 pH units, and loss of gasses such as oxygen and carbon dioxide. The formation of ice is associated with an increase in volume and can result in a build-up of substantial pressure, which can cause cracking of some foods.

During freezing, cells and tissues may be protected from damage by certain solutes, a process known as *cryoprotection.* In addition to affecting the quality of frozen foods, cryoprotectants are also likely to protect microorganisms against damage during freezing. Some foods naturally contain cryoprotectants and these are present in foods such as dairy desserts. Cryoprotectants that may be present naturally in, or may be added to, frozen foods include sugars, salts, polyhydric alcohols, and glycerol, the last being the most effective. The commercial production of frozen surimi (a minced, white fish product that has been subjected to washing processes to remove soluble materials) depends on the addition of cryoprotectants to preserve the gel-forming characteristics.[75] The cryoprotectants used in surimi are typically a mixture of sucrose, 4%(w/w); sorbitol, 4%(w/w); and tripolyphosphates, 0.2%(w/w).

6.4 THE EFFECT OF FREEZING ON MICROORGANISMS

6.4.1 General Comments

Experiments using simple aqueous suspensions have enabled investigation of the factors that affect survival of microorganisms during freezing and thawing, and their enumeration. In many cases, these experiments have been made with the aim of preservation of microorganisms by freezing, but they provide information that is relevant to the survival of microbes in frozen foods. At temperatures above 0°C, a sudden decrease in temperature can cause "cold shock," associated with damage to some bacteria. This usually only affects microorganisms in the logarithmic phase of growth and may only be of minor importance in freezing foods. While experiments in aqueous suspensions can provide information relevant to microorganisms within the matrix of foods, microbes at the surface of solid foods may also be subjected to drying effects during freezing.

6.4.2 Mechanism of the Effect of Freezing

During freezing of aqueous suspensions of microorganisms the microbes become concentrated in the unfrozen portion of the solution where they are subjected to the effect of concentrated solutes. As the temperature is reduced and more water is frozen, the increase in solute concentration in the unfrozen liquid results in diffusion of water from the microbial cells.

During freezing and thawing, factors that might be expected to cause damage to microorganisms include (1) low temperature, (2) extracellular ice formation, (3) concentration of extracellular solutes, (4) intracellular ice formation, and (5) concentration of intracellular solutes. The influence of these factors will be affected by the rate of freezing and thawing.

Temperatures below 0°C are not necessarily lethal to microbes provided that the cells and their environment do not freeze.[68] For example, about 100% of cells of *Saccharomyces cerevisiae* survived in suspensions cooled to –16°C when the extracellular water was supercooled and rapid cooling of a suspension of *Escherichia coli* to –9°C or –10°C caused no loss of viability provided that the cells remained supercooled.[68] In nonhalophilic microbes the molal concentration of intracellular solutes is usually less than 1 and the freezing point would, therefore, be between 0° and –2°C. In practice, during freezing of a suspension of microbes the external water freezes before the cell contents, which usually remain unfrozen above –5°C and often above –10°C. This may be due in part to supercooling of intracellular water[68] and in part to an increase in concentration of intracellular solutes. As the temperature is reduced, more water is frozen and the increase in solute concentration in the unfrozen liquid tends to result in diffusion of water from the microbial cells. Thus, the supercooled cell is subjected to two competing effects: (1) the increased concentration of extracellular solutes, which tends to cause intracellular water to diffuse from cells, and (2) the lowered temperature, which increases the tendency to formation of intracellular ice. If water cannot diffuse out of the cell sufficiently rapidly it will become increasingly supercooled and likely to freeze. Thus, the response of microorganisms to freezing is determined largely by the permeability of the cell to water, its size, and its surface-area-to-volume ratio. Injury to *S. cerevisiae* during freezing is probably due both to an increased intracellular concentration of solutes and to intracellular freezing.[68] Very low rates of cooling will lead to intracellular concentration of solutes but not to intracellular ice formation, whereas at cooling rates of between 10°C and 100°C, there is evidence of formation of intracellular ice crystals. In the case of *E. coli,* intracellular freezing is only likely to occur at freezing rates of 100°C min^{-1} or higher, and most low temperature damage during freezing at lower rates than this, and during frozen storage, is thought to be due to the effect of concentrated extracellular solutes, especially sodium chloride.[68] In some species of molds, eg, *Penicillium expansum,* freezing in growth medium at a cooling rate of 2°C min^{-1} resulted in shrinkage of hyphae, whereas at a higher cooling rate, eg, of about 20°C min^{-1}, resulted in intracellular ice formation.[73] For a range of species the rate of cooling during freezing that resulted in the presence of intracellular ice differed between 4°C min^{-1} and 53°C min^{-1}. Some species, including *Aschersonia alleyrodis*, *Phytophthora nicotianae,* and *Volvariella volvacae,* showed shrinkage at all the cooling rates examined (10°–100°C min^{-1}), and intracellular ice was not observed. Cryogenic freezing may give cooling rates of 100°C min^{-1} at the surface of some foods, but usually the cooling rate during freezing is likely to be substantially lower than this.

Injury and death of cells during freezing and frozen storage depends on time and temperature. In general, at very low temperature injury accumulates slowly, the rate of injury increasing with increasing temperature to reach a maximum near, but not at, the freezing point. The rate of injury during thawing may not be the same as that during freezing.

6.4.3 Factors That Affect the Survival of Microorganisms during Freezing and Thawing

Studies of the survival of microorganisms in simple aqueous systems have shown the ways in which specific factors can influence survival. Factors that may be involved are shown in Exhibit 6-1.

Exhibit 6-1 Factors Affecting the Survival of Microorganisms during Freezing and Thawing

- Type and strain of microorganism
- Nutritional status
- Phase of growth
- Composition of cooling and freezing medium
- Rate of cooling
- Holding temperature
- Time held at low temperature
- Rate of warming to melting point
- Dilution medium prior to viable count
- Method of determination of viable count
- Medium used for determination of viable count

Type and Strain of Microorganism

Bacterial spores are usually very resistant to freezing and thawing, therefore, a high proportion survive in most conditions. In general, Gram-positive bacteria are more resistant than Gram-negative organisms. Following rapid freezing of spores of *Bacillus mesentericus* to −70°C in water and subsequent thawing, about 90% of the spores remained viable.[47] The survival rates of vegetative bacteria in the same conditions were as follows: *Pseudomonas aeruginosa*, 18%; *Escherichia coli* 58%; *Staphylococcus aureus*, 96%, while that of *Saccharomyces cerevisiae* was 11%.

It is difficult to assess quantitatively the effect of freezing on the survival of filamentous fungi because of the complexity of the "colony-forming unit." In favorable conditions high rates of survival can occur. After cooling suspensions of a range of fungi in growth medium to −196°C at optimum cooling rates (from 1°C min^{-1} to 200°C min^{-1} depending on species), the estimated percentage recovery ranged from 27% to approximately 100%.[73] Free-living amoebae and most ciliated protozoa are relatively susceptible to freezing.

Nutritional Status and Phase of Growth

The nutritional status and phase of growth of microorganisms can influence their resistance to freezing and may have a small effect on their survival during freezing of foods. Studies of chemostat-grown cells of *E. coli* indicated a general correlation between carbohydrate content and survival during freezing.[15] In the case of frozen starter cultures and frozen doughs, a high rate of survival of microbes is desirable, and growth conditions may be controlled to ensure good survival. Growth of a commercial strain of baker's yeast, *Saccharomyces cerevisiae,* with controlled substrate feeding (fed-batch culture) was the major factor that conferred resistance to freezing; strong aeration in addition to fed-batch culture gave the highest resistance with up to 92% survival of cells freeze thawed to −50°C for 10 minutes in water.[44] In cultures grown in highly aerobic conditions, a high trehalose content was correlated with resistance to freezing. Trehalose has been recognized as a particularly effective cryoprotective carbohydrate; its effect has been attributed to membrane stabilization. The fact that the correlation between trehalose content and cryoresistance only occurred in cells grown in optimum oxygenation indicated the existence of another cryoprotective factor more important than trehalose.

Composition of Cooling and Freezing Medium

The effects of increasing concentrations of extracellular solutes on bacteria during freezing are minimized if the cells are suspended in distilled water. The survival of some Gram-negative bacteria is lower in NaCl solution than in water and death rates during storage are higher at temperatures above the eutectic point of the medium than below it. When a suspension of *E. coli* in NaCl, 0.85% (eutectic temperature −21.8°C) was cooled to between −7° and −18°C, the survival after 24 hours was reported as 10%, whereas at lower temperatures 30% to 40% of cells survived.[68] Washed, chemostat-grown (ie, log phase) cells of a strain of *E. coli*, frozen to temperatures below −20°C in saline, showed much lower viability than those frozen in water (Figure 6-4).[14]

Cells frozen to −70°C at a range of cooling rates showed much lower viability in saline than in water (Figure 6-5).[14]

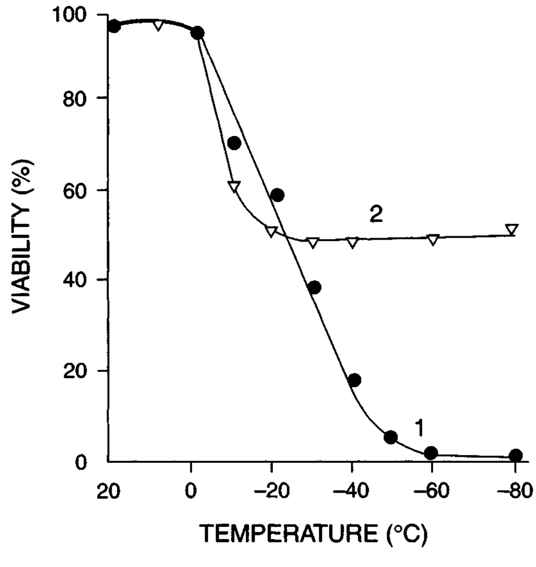

Figure 6-4 Effect of Temperature of Freezing in Distilled Water (curve 2) and in 0.85% Saline (curve 1) on Viability of *E. coli*. The bacterial suspensions were cooled at 25°C min^{-1} to various temperatures and thawed rapidly. Viability was determined by slide culture. *Source:* Reprinted with permission from P.H. Calcott and R.A. Macleod, Survival of *Escherichia coli* from Freeze-Thaw Damage: A Theoretical and Practical Study, *Canadian Journal of Microbiology*, Vol. 20, pp. 671–681, © 1974, NRC Research Press.

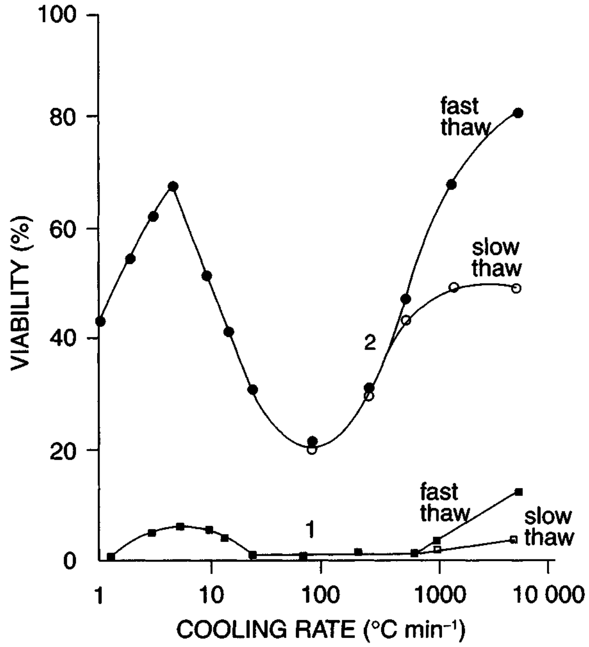

Figure 6-5 The Effect of Cooling and Warming Rates on Survival of *E. coli* Suspended in Distilled Water (curve 2) or in 0.85% Saline (curve 1). Suspensions were frozen to at least −70°C. Viability was determined by slide culture. *Source:* Reprinted with permission from P.H. Calcott and R.A. Macleod, Survival of *Escherichia coli* from Freeze-Thaw Damage: A Theoretical and Practical Study, *Canadian Journal of Microbiology*, Vol. 20, pp. 671–681, © 1974, NRC Research Press.

Glycerol and sucrose can act as cryoprotectants and protect *E. coli* against the lethal effects of freezing in water (Figure 6-6) and in saline (Figure 6-7).[14]

This protective effect may be due both to the fact that the fraction of the molarity contributed by the NaCl will be reduced and to the fact that the nonelectrolytes may protect the cells against the effect of the electrolyte.[68]

In contrast to *E. coli, Streptococcus faecalis* was resistant to the presence of NaCl during freezing,[16] and saline had a protective effect on *Saccharomyces cerevisiae.*[68]

Survival of bacteria may be reduced in an acidic medium. Thus, adjustment of the pH of trypticase soy broth from pH 7.3 to pH 3.8 with HCl decreased survival of *Staphylococcus aureus* during freezing to −30°C by eight-fold and a high proportion of the survivors were sublethally injured.[71]

The Effect of Rate of Cooling

Figure 6-5 shows the effect of rate of cooling during freezing of *E. coli* in water to −70°. Maximum

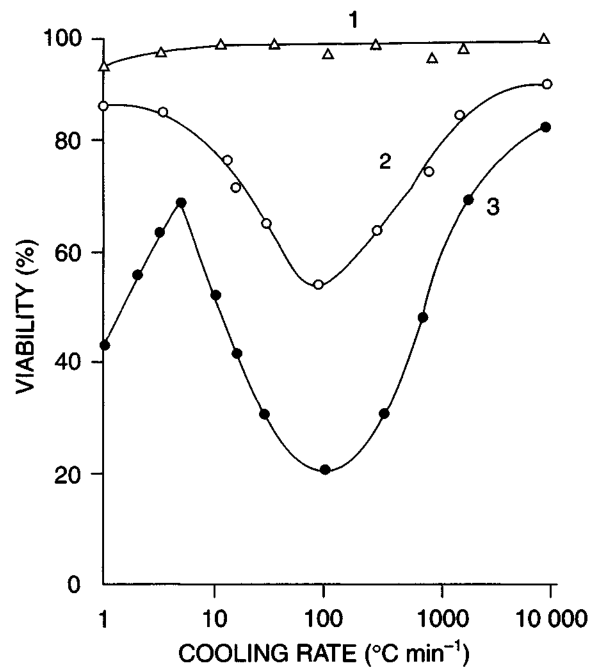

Figure 6-6 Protection of *E. coli* by Glycerol from Freeze-Thaw Damage in Distilled Water. Procedure as in Figure 6-5, except that the bacteria were frozen in distilled water + 3% glycerol (curve 1), + 1% glycerol (curve 2), or distilled water alone (curve 3). Viability was determined by slide culture. *Source:* Reprinted with permission from P.H. Calcott and R.A. Macleod, Survival of *Escherichia coli* from Freeze-Thaw Damage: A Theoretical and Practical Study, *Canadian Journal of Microbiology,* Vol. 20, pp. 671–681, © 1974, NRC Research Press.

survival occurred at a cooling rate of 6°C min^{-1}, and the viability dropped at cooling rates lower and higher than this. As discussed earlier, the rate of freezing of foods will usually be lower than 100°C min^{-1} and often lower than 10°C min^{-1}. The effects of different rates of cooling may be obscured by the effects of protective factors.

Holding Temperature and Time Held at Low Temperature

The majority of reports indicate that the rate of death of bacteria during frozen storage is usually greatest just below the freezing point. The sensitivity of bacteria to freezing was found to be correlated with sensitivity to storage in the frozen state.[47] When spores of *Bacillus mesentericus* in water were stored for 133 days at temperatures from –1° to –20°C, between 50% and 100% remained viable, whereas the decrease in viability of the other bacteria tested was *Staphylococcus aureus* < *Escherichia coli* < *Pseudomonas aeruginosa,* the decrease in viability being greatest at the highest temperature (Figure 6-8).

Usually the decrease in viability is very small at temperatures of –60°C and below.

Rate of Warming to Melting Point

After relatively low rates of cooling, such as are used in freezing of foods, the rate of warming is reported to have little effect on survival of bacteria or yeasts.[13] After rapid cooling, fast warming is more protective than slow warming.

Techniques Used for Determination of Viable Count

Freezing and thawing can result in sublethal damage to microorganisms, making them unable to multiply on selective media (Chapter 15). In many cases, therefore, it is necessary to resuscitate damaged microorganisms to estimate the number that remain viable in frozen foods (Section 6.6). Usually suble-

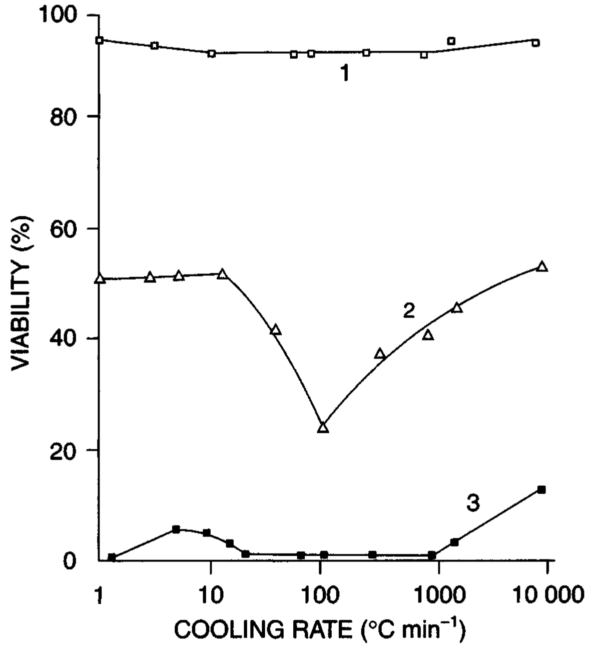

Figure 6-7 Protection of *E. coli* by Glycerol from Freeze-Thaw Damage in 0.85% Saline. Procedure as in Figure 6-5, except that the bacteria were frozen in saline + 3% glycerol (curve 1), + 1% glycerol (curve 2), or saline alone (curve 3). *Source:* Reprinted with permission from P.H. ---

thally damaged bacteria grow more readily on complex nutrient media than on minimal media.

6.5 EXAMPLES OF THE EFFECT OF FREEZING ON MICROORGANISMS ASSOCIATED WITH FOODS

The following examples are chosen to illustrate the survival of different types of microorganisms, including the most resistant and the least resistant foodborne pathogenic bacteria, in foods.

6.5.1 Bacterial Spores

The resistance of spores to freezing and frozen storage was illustrated by work showing that quick or slow freezing of spores of *Clostridium botulinum* type B in phosphate buffer or in pea juice (pH 7.1) had

Next Page

no effect on viability; repeated freezing and thawing also had little or no effect on the toxin.[57] Both *C. botulinum* spores and toxin survived freezing in fruits and vegetables and storage for 1 year at –16°C.[115] Whereas in food, *C. botulinum* toxin appears to retain activity after freezing and thawing, crystalline type A toxin in 0.05 M acetate buffer pH 4.2, which retained its activity at +4°C for 1–2 years, was completely detoxified by freezing.[93]

6.5.2 Gram-Positive, Vegetative Bacteria

In a study involving both Gram-positive and Gram-negative bacteria, it was reported in 1938 that after inoculation of a high number of the organisms into ice cream, *Brucella abortus* and *Salmonella enteritidis* survived during storage at –23.2°C for 7 years.[114] Other strains of *Brucella* and *Salmonella* and *Mycobacterium tuberculosis hominis* and *M. tuberculosis bovis* were still viable after between 4 and over 6 years. The author pointed out that because of the high inoculum used and the fact that commercial ice cream (in the US) was made from pasteurized milk, the practical importance of these results should not be emphasized. It is interesting, however, to recognize the possible longevity of these organisms in ice cream.

Reports that vegetative cells of *Clostridium perfringens* were found in fresh meat more frequently than the spores gave rise to studies of the survival of vegetative cells of this organism in frozen meat products.[112] In fresh meat products inoculated with vegetative cells and spores of *C. perfringens* and frozen at –29°C, the number of viable spores remained practically unchanged for 42 days. The number of vegetative cells decreased by between 38% and 75% in 1 day, then declined slowly to give a decrease of about 89.5% in 42 days. In Ellner's medium frozen at –29°C, the number of viable spores remained unchanged, whereas the number of vegetative cells decreased by 99.5% in 42 days. A further study gave similar results, showing that after freezing in a meat medium at –23°C and storage for 14 days, the numbers of viable vegetative cells decreased by 94%.[43]

After freezing in whole milk and storage at –20°C for up to 231 days the number of viable *Staphylococcus aureus* decreased by only about 10%.[7] During storage of raw, minced beef at –22°C for 4 months the numbers of *S. aureus* decreased by 91%, ie, by about one log cycle,[71] and in frozen beef or chicken stored at –18°C for 168 days, the numbers also decreased by about one log cycle.[117] In lean ground beef with a pH in the range 4.6–6.3 the numbers of viable *S. aureus* were reported to remain stable throughout four cycles of freezing in a mixture of dry ice/ethanol and thawing, but in beef adjusted to pH of 4.2, a decrease of just over one log cycle occurred.[29] *Staphylococcus* enterotoxin is not inactivated by freezing.

Freezing and frozen storage of *Listeria monocytogenes* for 1 month at –18°C in phosphate buffer or in Tryptose broth caused death of 54% to 87% of cells

Table 6-5 The Effect of Temperature of Freezing, Frozen Storage, and Suspending Medium on Survival of *Listeria monocytogenes* Strain Scott A

			Suspending Medium	
Treatment	*Freezing*	*Storage*	Phosphate Buffer, *0.1 M, pH 7*	Tryptose Broth
1	–18°C, 30 minutes	–18°C, 4 weeks	87% cells dead 10.3% cells injured* 2.7% cells uninjured	54% cells dead 21% cells injured 25% cells uninjured
2	–198°C, 1 minute	–198°C, 4 weeks	0 cells dead 0 cells injured 100% cells uninjured	15.5% cells dead <0.8% cells injured 83.7% cells uninjured
3	–198°C, 1 minute	–18°C, 4 weeks	60% cells dead 14% cells injured 26% cells uninjured	61% cells dead 17.2% cells injured 21.8% cells uninjured

*% of cells that were injured, determined from the number of bacteria that formed colonies on Tryptose agar and the number that formed colonies on Tryptose agar plus 16% NaCl.

Source: Data from S.E. El-Kest et al., Fate of *Listeria Monocytogenes* During Freezing and Frozen Storage, *Journal of Food Science*, Vol. 56, pp. 1068–1071, © 1991, Institute of Food Technologists.

and injury of others, whereas freezing and storage for 1 month at −198°C had little lethal effect (Table 6-5).[35,36] Further death and injury occurred during longer storage at −18°C but not at −198°C.

The addition of up to 4% of glycerol, milk fat, or lactose and up to 2% casein to phosphate buffer had a protective effect during freezing and storage at −18°C.[34] A protective effect of food was shown by work in which the *L. monocytogenes* was added to ground beef (pH 5.84) that had been irradiated to reduce the background microflora[80]; after freezing to −18°C and subsequent storage at this temperature for 14 weeks the number of *L. monocytogenes* was unchanged. Comparison of numbers on Tryptose phosphate agar + 1% sodium pyruvate (designed to allow multiplication of damaged bacteria), and on Tryptose phosphate agar + 5% NaCl (designed to allow multiplication of undamaged bacteria only) showed no evidence that cells were damaged. Similar results were obtained in other foods with a pH higher than 5.8 but in tomato soup (pH 4.74) the numbers of *L. monocytogenes* tended to decline slightly during storage at −18°C and a high proportion of the cells were sublethally damaged; this resulted in lower counts on selective than on nonselective media.

L. monocytogenes has been found in many samples of ice cream, ice milk, and related frozen products,[35] and in the US this has led to many voluntary, Class 1 recalls of products. Following inoculation into ice cream to give about 0.5 colony-forming units per ml of mix, *L. monocytogenes* strain Scott A showed no significant decrease in numbers during storage at −18°C for 5 months, and could be recovered readily by selective as well as nonselective enrichment procedures.[62] The survival (measured by counting on a selective medium) of *L. monocytogenes* during freezing of ice cream and storage at −18°C was reduced significantly by the incorporation of sufficient nisin to give a concentration of 400–500 IU g^{-1},[27] but the possible presence of sublethally damaged listerias was apparently not investigated.

Because of the short, seasonal nature of the milking period for ewes and goats, freezing is used as a means of storage of cheese curd after drainage, and of ewes' and goats' milk in Greece, France, Italy, and Spain in order to extend the period of manufacture of cheese. Experiments in which *L. monocytogenes* was added to ewes' milk showed that a high proportion of the bacteria (>95% of strain Scott A and and 40%–50% of strain CA) could survive in the milk during frozen storage at −18° or −38°C for over 7 months.[81] In Feta cheese curd samples (pH 5.43) numbers of strain Scott A decreased by *ca.* 50% in the center of the cheese and by *ca.* 22% on the surface after storage at −18°C for 7.5 months, whereas numbers of strain CA at the center and at the surface had decreased by *ca.* 98%.

These results indicate that Gram-positive bacteria often show a survival rate of between 10% and over 90% during freezing and frozen storage in nonacidic foods, whereas in foods with a low pH or that contain inhibitors a lower rate of survival may occur.

6.5.3 Gram-Negative Bacteria

Although, in general, Gram-negative bacteria are less resistant to freezing than Gram-positive organisms, nevertheless they may survive well in frozen foods depending on the protective effect of those foods. The survival of pathogens such as *Salmonella* species and verocytotoxigenic *Escherichia coli* in frozen foods is of particular concern because of the low numbers that can cause disease.

In fish frozen at −22°C and stored at −17.8°C for over a year, 10% of the inoculum of *S. typhimurium* remained viable.[84] Comminuted beef protected *S. typhimurium* during storage at −20°C and no marked decrease in viable count was detected after 90 days, although daily freeze-thaw cycling from −20°C to −4°C to −20°C resulted in a decrease of about 1,000-fold in viable count.[45] Heat denatured meat suspensions were less protective, and adjustment of the pH of such a suspension to 5.8 or 4.25 increased inactivation in 20 days at −20°C by about 100-fold compared with very little inactivation at pH 7.5. After storage in beef sausage and in cooked, minced beef at between −18° and −20°C for up to 10 weeks, the viable count of *S. typhimurium* on a nonselective medium had decreased by less than 10-fold.[8] Comparisons of viable counts on a nonselective medium and on a selective medium showed that before freezing 5% of the bacteria in minced beef and 36% in beef sausage were sublethally damaged, whereas after freezing and frozen storage the proportion had increased to 30% in minced beef and 45% in the beef sausage mix.

Following inoculation of *E. coli* O157:H7 into ground beef, which was then formed into patties, maintained at −80°C for 30 minutes and stored at −20°C for up to 9 months, little if any decrease in viable numbers occurred during freezing and storage.[31]

Campylobacter jejuni is usually relatively sensitive to adverse conditions but in a survey of fresh and frozen meat and poultry samples collected at the point of slaughter, *C. jejuni* was isolated from 12.1% of fresh samples and from 2.3% of frozen samples.[105] The organism has been detected in frozen chickens from supermarkets and can survive for extended periods in frozen meats.[1] After inoculation into ground beef, which was then frozen at –15°C, the number of *C. jejuni* had decreased approximately 1,000-fold at the first time of sampling (3 days) but then remained unchanged for up to 14 days.[106] Survival was increased by the addition of cryoprotective agents such as 10% glycerol. In brucella broth frozen at –18°C, the numbers of viable *C. jejuni* decreased by about 100-fold within 5 days; the presence of 3% NaCl in the broth reduced the number of survivors by about 50-fold.[1] In raw or cooked chicken and in beef and cod at –18°C, the decrease in viable count was less than that in the broth and NaCl had less effect.

Studies of the survival of *Vibrio* species in frozen seafood have indicated a marked decrease in numbers during storage. In a study of the survival of *Vibrio cholerae* in frozen seafood homogenates log-phase cells were inoculated into the sterilized homogenate and viability after storage was assessed by an MPN method after enrichment in alkaline peptone medium.[87] The use of log-phase bacteria might be expected to give a minimum estimate of resistance to freezing. After freezing and storage at –20°C for 21 days the log number of viable *V. cholerae* had decreased by approximately 3.0, 5.5, and 5.0 in oyster, shrimp, and crab meat, respectively.

After inoculation into oysters and freezing at –15°C or –30°C, the numbers of *V. parahaemolyticus* decreased by up to 10-fold during freezing and then in an approximately log linear way during storage.[58] After storage for 100 days at –15°C the log numbers of viable vibrios had decreased by approximately 3 to 4, while at –30°C the log numbers had decreased only by about 1.5. From studies of the survival of *V. parahaemolyticus* in an oyster meat broth at –18°or –24°C, times for reduction in numbers from 10^2–10^4 g^{-1} to below about 1 g^{-1} were calculated as about 9 to 10 weeks.[77]

In shrimp homogenate inoculated with *V. parahaemolyticus* or with *V. vulnificus* then frozen and stored at –20°C, the numbers of these bacteria had decreased by about 10^6 in 40 days.[11] On the basis that the number of these bacteria in market fish and crustacea is usually fewer than 10^3 g^{-1}, and the fact that the infectious dose of *V. parahaemolyticus* is considered to be relatively high, the authors suggested that frozen storage of shellfish at –20°C offered considerable protection to the consumer.

Following inoculation of *V. vulnificus* into freshly harvested, shucked oysters, which were then packed in plastic bags under air or under vacuum and frozen at –20°C in a laboratory freezer, the number of viable *V. vulnificus* decreased by about 4 logs in 30 days under air and by over 3 logs under vacuum, whereas after 70 days a similar decrease, of just under 5 logs, occurred in both types of packaging.[82] Substances that protected *V. cholerae* during storage at –20°C were obtained from prawn shells and were much more active than other cryoprotective substances such as 10% glycerol.[96]

Despite the fact that some of the above reports indicated a relatively rapid decline in the numbers of *Vibrio* species during frozen storage of seafood, in a survey of 114 samples of frozen seafoods available in Taiwan, *V. cholerae* was recovered by enrichment from 14.9%, *V. parahaemolyticus* from 15.8%, and *V. vulnificus* from 3.5%.[120] In tryptic soy broth plus 1% NaCl frozen rapidly and stored at –30°C, the numbers of viable *V. cholerae* decreased by 100-1,000-fold in the first day and declined more slowly for a further 2 days, whereas freezing in shrimp homogenate resulted in a gradual decrease of approximately 10-fold in 3 days.

6.5.4 Yeasts and Molds

Although some experiments have shown that *Saccharomyces cerevisiae* was less resistant to freezing than *Escherichia coli*, this resistance may be increased by control of conditions during growth. The resistance of this yeast to freezing is of particular importance in the production of frozen, yeast-leavened doughs. After growth in fed-batch cultures in strongly aerobic conditions the organism showed *ca.* 100% survival in dough frozen to –50°C at a freezing rate of 20°–42°C min^{-1}.[44]

6.5.5 Viruses

Evidence from experiments in which foods were inoculated with viruses indicates that these can be very resistant to freezing. In various foods frozen at –20°C poliovirus and type B1 and B6 coxackieviruses decreased by a factor of less than 10 during storage for 5 months.[65] In oysters frozen at –36°C and stored at –17.5°C, approximately 91% of poliovirus was viable after 2 weeks and 10% survived after 12 weeks.[30] In prawns frozen and stored at –17.5°C, more than 10% of polio 1 virus survived for 300 days.[39]

6.5.6 Protozoa

There is little published information concerning the ability of protozoa to survive in frozen foods. An anecdotal report described infection with *Cryptosporidium* species apparently as a result of the ingestion of frozen tripe contaminated with oocysts.[89]

Oocysts, 10^5 in 100 μl water, were killed by snap freezing in liquid nitrogen but when exposed to slow freezing at −22°C, 33% remained viable (as judged by *in vitro* excystation and exclusion or inclusion of two fluorogenic vital dyes) after 21 hours and 1.8% remained viable after 775 hours.[89] After freezing 8×10^6 oocysts in 400 μl deionized water, all oocysts frozen at −70°C appeared to be noninfectious and cryoprotectants failed to prevent this inactivation.[40] When oocysts were frozen at −10° for up to 168 hours, −15° for up to 24 hours, and −20°C for up to 5 hours a proportion remained infective. The authors concluded that ice cubes prepared in the freezing compartment of a home refrigerator cannot be relied on to be free of *Cryptosporidium* even if frozen for longer than 24 hours, and that if oocysts are frozen in a medium containing organic materials or minerals or exposed to temperatures higher than −10°C they might survive for a longer period.

Freezing can be used to inactivate cysts of *Toxoplasma gondii,* which may be present in meat, particularly pork. These cysts are more readily inactivated than are the larvae of *Trichinella spiralis.*[60] Following inoculation into pigs, which were killed 42 to 69 days after inoculation, and the meat stored at −6.7°C for up to 11 days, viable cysts were still present in the meat as determined by inoculation of mice, but after storage at a temperature of −9.4°C or lower for 64 minutes, meat was no longer infective.[60]

6.5.7 Parasites

Because meat is liable to be eaten undercooked, freezing has been used for many years to inactivate the nematode *Trichinella spiralis* in pork and pork products. From studies of the effect of freezing on meat from pigs infected with *T. spiralis,* it was concluded that freezing to −29°C using cryogenic equipment would immediately render pork and pork products free of this parasite.[92] For this purpose the US Code of Federal Regulations[21] specifies freezing at −15.0° for 20 days, −23.3° for 10 days, or −28.9°C for 6 days for pork less than 15.2 cm diameter and longer for products with a greater diameter. Further information is available concerning the combinations of time and temperature required.[59] The European Union also requires that every imported pig carcass that has not been inspected for *Trichinella* must be submitted to a freezing procedure, eg, storage at −25°C for 240 to 480 hours, depending on the size of the cut or carcass, in order to destroy the larvae.

In sausages and certain other pork products, the USDA Certification Program recommends freezing the meat for specified times in order to inactivate *Trichinella spiralis.*[21] In order to obtain precise time/temperature data a study was made in which pigs were inoculated with larvae of *T. spiralis,* slaughtered about 45 days after inoculation, the meat was homogenized, pressed to 2 mm thickness, packed into pouches, and frozen.[59] The concentration of larvae in the meat was estimated as >1,000 infective larvae per g. The survival of viable larvae was assessed by infectivity in rats. In these conditions, where heat transfer was very effective, maintenance at −23.3°C for 1 second with a come-down time of 5 minutes and a come-up time of 2 minutes resulted in complete destruction of infectivity.

Freezing is also used to kill the larvae of nematodes of the family *Anisakidae,* which can cause disease in humans as a result of the consumption of infected raw or inadequately cooked fish or other seafood. After freezing infected fish at −20°C, 100% inactivation of larvae was reported in 1 to 5 days.[28] In the Netherlands, where cases of infection have resulted from the consumption of "green herring," a fresh raw herring sometimes slightly salted, legislation requiring all freshly caught herring to be frozen prior to selling has been introduced as a means of control.[55]

6.6 THE MICROBIAL FLORA OF FROZEN FOODS

In order to detect viable microorganisms in frozen food by direct plating or enrichment there is a need to allow the recovery of sublethally damaged microbes. This is particularly important in the case of pathogenic bacteria that, if present, are likely to be found only in low numbers and therefore selective media are required to detect them. In tests for the presence or absence of pathogenic bacteria, particularly Gram-negative organisms, resuscitation is advisable before selective enrichment. Methods for resuscitation of damaged microorganisms are discussed in Chapters 15 and 62. In order to assess numbers of viable bacteria, samples can be plated on a membrane overlaid on a resuscitation medium and after incubation to allow recovery of damaged organisms the membrane is transferred to the surface of a selective medium.[2,52] In a cheaper, alternative method a diluted sample of the frozen food was transferred to a Petri dish to which a solid resuscitation medium (eg, a medium containing yeast extract, tryptone, sodium pyruvate, sodium glycerophosphate and magnesium sulphate) was added.[49] After a short incubation period, the medium was overlaid with a selective medium. Use of this type of method increased the numbers of *E. coli* detected in frozen meat and poultry products by a factor of at least 2 compared with counts directly in or on a selective medium.[49] The resuscitation medium of Hall[49] also gave a higher count of mesophilic, aerobic bacteria in frozen foods than Plate Count Agar, which is widely used in estimation of the number of these bacteria in frozen foods.[79]

Foods that are heat treated before freezing include vegetables, prepared meals, some meat products, and some fish products. In these foods many of the microorganisms present at freezing are derived from processing equipment, air, or personnel. In the case of foods that are not heat treated before freezing, the microorganisms on the frozen product will include a high proportion of those on the fresh food together with contaminants from the factory environment.

The blanching treatment given to many vegetables before freezing kills the majority of vegetative bacteria present and can reduce the count of aerobic bacteria from about 1×10^6 g^{-1} to about 10^2 g^{-1}.[70] The major groups of bacteria present on these vegetables after freezing differ from those that are present on fresh vegetables. In a large US study of peas, snap beans, and whole-kernel corn during preparation for freezing, the main groups of microorganisms in the final product were Gram-positive, catalase-negative cocci, which gradually became predominant in products after 15 or more days of processing.[99] These bacteria probably became established on equipment such as slicers, conveyers, inspection belts, and filling machines.[12] The cocci appeared to be heterofermentative leuconostocs, lactic streptococci, and enterococci; this last group was not considered to have any sanitary significance and similar bacteria have been isolated from fresh vegetables. In a study of frozen peas in the UK in the early 1960s, in which the number of aerobic bacteria was usually between 10^4 and 10^6 g^{-1}, most of the bacteria were of two species, *Leuconostoc mesenteroides* and *Streptococcus lactis*.[116]

In a further extensive study of frozen vegetables in the US in 1977 the majority contained between 10^4 and 10^6 aerobic bacteria g^{-1}.[98] The number of fecal coliform bacteria detected was between 5 and 200 g^{-1}.[100] *E. coli* was only recovered from 29% of the fecal coliform-positive samples, the majority of isolates being *Klebsiella pneumoniae* or other coliforms often found on raw vegetables.

On commercial samples of frozen chicken, prawns, peas, and sliced green beans the numbers of aerobic, mesophilic bacteria, assessed on Plate Count Agar without resuscitation, were between 2.25×10^4 and 2.25×10^5 g^{-1}.[79]

High numbers of microorganisms may be present in ice cream and similar products. In the UK, the following microbiological criteria are applied to ice cream (where n = number of sample units; c = number of sample units where the bacterial count may be between m and M; m = the threshold value, the result is satisfactory if the number of bacteria in all the sample units does not exceed m; M = the maximum number of bacteria, the result is unsatisfactory if the number of bacteria in one or more of the sample units exceeds M): an aerobic colony count, m = 100,000 g^{-1}, M = 500,000 g^{-1}, $n = 5$, $c = 2$; coliforms and *Staphylococcus aureus*, each $m = 10$ g^{-1}, $M = 100$ g^{-1}, $n = 5$, $c = 2$; *Salmonella*, absence in 25 g, $n = 5$, $c = 0$; *Listeria monocytogenes*, absence in 1 g, $n = 5$, $c = 0$.[53,104] A survey in the UK in 1993 of retail samples of ice cream and other edible ices showed that of about 1,000 samples of branded, hard ice creams only 1% had aerobic plate counts higher than 10^4 g^{-1} compared with 25% of 964 samples of unbranded hard ice creams (Table 6-6).[78] A low proportion of samples of unbranded hard ice cream and of soft ice cream did not meet the industry standards for *S. aureus*, *Salmonella* species, and *L. monocytogenes* and contained $>10^2$ *E. coli* g^{-1} or $>10^2$ *Bacillus cereus* g^{-1}, and one sample of "real-fruit" hard ice cream contained *S. enteritidis* PT4 (Table 6-7).

Packaged ice produced under conditions of poor hygiene may contain relatively high numbers of microorganisms. A survey in Iowa in 1991 showed that all of seven samples produced on the premises of a convenience store contained $>10^3$ bacteria ml^{-1}, and five of these contained $>10^4$ ml^{-1}.[76]

During the production of frozen foods, routine tests are used to monitor the general microbiological quality of the food and contamination with pathogenic bacteria, and to verify the effectiveness of hazard analysis critical control point (HACCP) control of the process. Methods of sampling and analysis were discussed in detail by Hall[48] and White and Hall.[118]

6.7 OUTBREAKS OF DISEASE ASSOCIATED WITH FROZEN FOODS

The incidence of illness due to the consumption of frozen foods is relatively rare, nevertheless these foods, in particular ice cream, have been responsible for some serious outbreaks and cases of disease (Table 6-8).

In the UK before the introduction in 1947 of statutory regulations regarding the heat treatment of ice

Table 6-6 Survey of Retail Samples of Ice Cream and Similar Products in the UK in 1993. Number (and %) of Samples with Counts of Aerobic Bacteria per Gram (on Plate Count Agar) within the Stated Ranges

		Range of Counts per Gram after Incubation at 30°C for 48 Hours						
Product	*Total Samples*	10^2–$<10^3$	10^3–$<10^4$	10^4–$<10^5$	10^5–$<10^6$	10^6–$<10^7$	$>10^7$	*Not Examined*

cream mix, ice cream was frequently a vehicle for transmission of pathogenic microorganisms. Many outbreaks were caused by *Staphylococcus aureus* enterotoxin. *Staphylococcus aureus* from nasal and hand carriers contaminated the mix and multiplied and formed toxin before freezing. In one outbreak associated with ice cream, more than 700 people were affected by *S. aureus* enterotoxin.[51] The last major outbreak in the UK due to contaminated ice cream occurred in 1946, when about 210 cases of typhoid fever including four deaths were reported in Aberystwyth.[38] The ice cream was contaminated by the manufacturer who was a urinary excreter of *Salmonella typhi*, but had been declared free of infection in 1938. Following this outbreak, in 1947 legislation requiring pasteurization of ice cream mix was introduced in the UK.[51] Outbreaks and cases of disease due to the consumption of ice cream continue to be reported from many countries. Frequently these cases have been caused by *Salmonella* species and associated with the use of raw egg and failure to pasteurize the ice cream mix. Despite the fact that commercial production of ice cream in the UK is controlled by legislation that specifies pasteurization of the ice cream mix, this does not apply to homemade products, recipes for which in books and magazines often contain fresh eggs and involve little or no heat treatment.

In 1967 in the US, a common source outbreak of infection with *S. typhimurium* affected people at 14 separate banquets.[5] Epidemiological evidence indicated that the outbreak was due to an imitation ice cream produced by a single company that specialized in kosher desserts, and the product had been made from unpasteurized egg yolk that had not been heated during production of the ice cream. *S. typhimurium* was isolated from leftover samples of the frozen dessert and, together with two other species of *Salmonella*, from four unopened cans of unpasteurized, frozen, sugared egg yolks sampled from the manufacturer. It was estimated that 1,790 people who attended these banquets became ill, and the total number affected by products from this manufacturer may have been much higher.

During the period 1966–1976, 22 outbreaks involving 292 individual cases of salmonellosis associated with the consumption of homemade ice cream

were reported to the US Centers for Disease Control.[46] *Salmonella typhimurium* was associated with 12 of these outbreaks, *S. enteritidis* with five, and five were associated with other salmonellae.

In an outbreak of typhoid fever in Trinidad in 1971, the majority of cases occurred in children aged 5 to 14, and epidemiological evidence implicated a commercially prepared ice cream made without pasteurization; it was suspected that an infected carrier of *S. typhi* was the source of the contamination.[107]

The consumption of homemade ice cream caused the death of a previously healthy teenager and severe illness in other members of a family in the US in 1982.[108] The ice cream contained about 10^6 *S. typhimurium* g^{-1}, and this was linked to the use of eggs from hens that carried *S. typhimurium* in the intestine and oviduct.

An outbreak in 1988 in the UK affected 18 out of 75 persons who attended a private function and were infected with *Salmonella enteritidis*; homemade ice cream prepared from raw shell eggs was implicated.[25]

In September 1991, the Public Health Laboratory Service in the UK received three reports of family outbreaks of *S. enteritidis* PT4 infection associated with the consumption of homemade ice cream.[72] In family outbreaks the food vehicle has often been consumed before an investigation of illness takes place, but in the 1991 UK outbreak shown in Table 6-8 the ice cream had been prepared using raw shell eggs and contained approximately 10^5 *S. enteritidis* PT4 per gram.[72]

An outbreak of illness due to *S. enteritidis* in the US in 1993 that affected 12 people was associated with the consumption of homemade ice cream made with raw eggs; *S. enteritidis* of the same phage type was isolated from patients and from the ice cream.[18]

The outbreak of infection with *S. enteritidis* in the US in 1994 that was attributed to a nationally distributed brand of ice cream, was reported as the largest common-vehicle outbreak of salmonellosis ever recognized in the US.[50] The pasteurized ice cream premix had been transported in tanker trailers that had previously hauled nonpasteurized liquid egg, which was contaminated with *S. enteritidis*. There was evidence that the trailers were not adequately cleaned after transporting the egg, and the ice cream premix was not repasteurized after transportation. Detailed analyses of samples associated with the outbreak indicated that betweeen 25 and 50 cells of *S. enteritidis* caused mild to severe illness, and that children experienced more severe symptoms than adults.[113] The total number of people thought to have been affected (about 22,400) was estimated on the basis of the attack rate in Minnesota, where the outbreak was detected, and the number of people nationwide who consumed the product during the relevant period of time.

Two outbreaks of infection with *S. enteritidis* reported in Germany in 1996 were attributed to the consumption of ice cream prepared in commercial bakeries.[110]

In an outbreak in 1987 in the UK in which six members of a family suffered food poisoning due to *Bacillus cereus* after eating homemade ice cream, the product was made with egg white and fresh cream and was reported to contain $>10^{10}$ *B. cereus* per ml.[101]

In January 1991, epidemic cholera spread to Piura in Peru and within 2 months caused 7,922 cases and 17 deaths.[88] Epidemiological studies indicated that the organism was spread in municipal drinking water and in food and beverages sold by street vendors; the use in those beverages of ice prepared in conditions of very poor hygiene was probably one of the causes of transmission.

In 1991, four cases of cholera in the US were caused by frozen coconut milk that was imported from Thailand and used to prepare a dessert.[109]

An outbreak of infection with *E. coli* O157 in 1997 in the US that affected 15 people was associated with the consumption of frozen ground meat patties and burgers.[20] These patties were not a ready-to-eat product, and an important critical control point in the production of such foods is adequate cooking before consumption in order to ensure that any surviving pathogenic microorganisms are killed.

Seventeen members of a group of travelers from Italy who had visited Thailand in 1988 showed symptomatic infection with *Entamoeba histolytica* and/or *Giardia lamblia*[61] while other members of the group were asymptomatically infected. Foods that were significantly associated with the infections were drinks with ice, ice cream, and raw fruit in ice. It was suggested that ice or ice cream was the vehicle for *Entamoeba histolytica,* whereas *Giardia lamblia* was transmitted in water used with the raw fruit and drinks.

In 1987, an outbreak of infection with Norwalk virus in the US was associated with consumption of commercial ice used in carbonated drinks.[17] The ice had been produced in an ice manufacturing plant from three wells, it was then treated with ultraviolet light before freezing. Prior to production of the ice, a torrential rainfall caused flooding of the manufacturer's wells and septic tank. Ice production was halted for 2 days and resumed after turbid water had been pumped out of the wells; the water was not chlorinated before production of ice was resumed.

Table 6-8 shows two outbreaks due to infection with hepatitis A virus. In the first, frozen raspberries were implicated and it was suspected that frozen raspberries had been implicated in several previous outbreaks.[86] The distributor blast-froze raspberries gathered from a number of farms, small holdings, and large private gardens. Berry picking was a seasonal occupation attracting large numbers of itinerant workers. Cases of illness due to hepatitis A were reported in the area at the same time that the fruit was being picked. It was presumed that the berries became contaminated during picking and/or packing, probably by a virus excreter among the pickers. The defrosted raspberries were used to prepare a mousse and, in contrast to strawberries, they were not generally washed prior to serving.

A second outbreak of hepatitis A infection occurred in the US in March 1997 and was associated with frozen strawberries.[19] The fruits had been harvested in Mexico and transported to California, where they were processed, packed, and frozen in April to May 1996.

Table 6-8 shows examples of outbreaks that have been documented and reported. It should be remembered that in many countries additional outbreaks have undoubtedly occurred that have either not been detected, or not investigated and reported.

6.8 MICROBIOLOGICAL SPOILAGE OF FROZEN FOODS

At –5°C, a frozen food containing ice in equilibrium will have an a_w of about 0.95, and at –10°C the a_w will be about 0.90. Consequently, any microorganisms capable of growing in these low temperatures in media or foods in which freezing has started must be capable of growth at low water activity. The minimum temperature at which growth of spoilage bacteria occurs is probably between –2° and –10°C, but reliable reports of growth between about –5° and –10°C were stated by Larkin and Stokes[63] to be rare. On agar media containing glycerol or glycerol plus ethylene glycol to prevent freezing two Gram-positive cocci, one Gram-negative rod, and four species of *Candida* grew at –2°C and the yeasts also grew at –4.5°C while three species of *Bacillus* grew at –7°C and two at –10°C.[63] In a liquid medium containing 10% glycerol to prevent freezing (a_w approximately 0.980) three strains of *Candida* species grew at –5° to –7°C, and five strains of *Bacillus* species grew at this temperature with generation times of 8.5 to 11.5 days. Growth of spoilage bacteria is not likely to be a problem in frozen foods maintained at temperatures of –12°C or lower, and would be very slow in foods maintained between –5° and –12°C. The presence of a high number of microorganisms on meat or fish before freezing may cause slow spoilage during frozen storage. This is due to the fact that although the microorganisms gradually die during storage of frozen foods, their enzyme systems, in particular lipases and lipoxidases, may remain active at temperatures down to –30°C.

Fish and other seafood from cold water environments may be heavily contaminated with psychrophilic and psychrotrophic bacteria. Experiments were reported to show that psychrophilic marine vibrios caused hydrolysis of protein and deterioration of quality in frozen fish and seafood stored at –20°C for 12 weeks[66]; the samples had been inoculated with the vibrios by dipping into a suspension containing 5×10^4 vibrios ml^{-1}.

Some molds are reported to grow on frozen foods at temperatures down to about –8°C.[94] Frozen meat transported for long distances by sea has been affected by a type of spoilage termed "black spot."[64] This has been attributed mainly to *Cladosporium herbarum*, but there is evidence that *Cladosporium cladosporioides*, *Aureobasidium pullulans*, and *Penicillium hirsutum* are also involved. "White spot" spoilage can occur on frozen meat and poultry and is caused mainly by *Chrysosporium pannorum*, but species of *Acremonium* and immature colonies of *Penicillium* species are reported to produce similar spoilage.[64] "Whisker-like" spoilage of meat is due mainly to *Thamnidium elegans* and occasionally to *Mucor racemosus* while the formation of blue-green colonies is due to *Penicillium* species, particularly *Penicillium expansum*. The minimum temperature for growth of these molds on meat was estimated as probably between –5° and –6°C.[64] Growth of these molds at –5°C is very slow; it was calculated that the minimum time for formation of a barely visible colony of *Cladosporium herbarum* at –5°C would be more than 4 months, and in a storage trial black spot colonies were only visible on meat after storage for 35 weeks.[64] In practical conditions it is thought that black spot, white spot, and blue-green mold develop as a result of the surface of meat reaching a temperature higher than –5°C in situations where surface dessication limits growth of spoilage bacteria. *Thamnidium elegans* is no more tolerant of low a_w than are spoilage bacteria, and "whiskers" spoilage by this mold probably occurs when temperature fluctuations lead to periodic defrosting of the surface of frozen meat and to high humidity from condensation.

On exposed muscle surfaces of frozen lamb carcasses stored for prolonged periods at –5°C, a yeast-dominated microflora was reported.[64] Yeasts were reported to multiply more rapidly than molds or bacteria on meat at –5°C, forming tiny, discrete colonies. The main yeasts present were *Cryptococcus laurentii* var. *laurentii*, *Cryptococcus infirmo-miniatus*, *Trichosporon pullulans*, and *Candida zeylanoides*. These yeasts have also been found in the microflora of turkeys stored for long periods at –2°C. Growth of a *Cryptococcus* species has been reported on frozen poultry at –5°C, and limited growth was reported at –7.5°C but not at –10°C.

6.9 CONCLUDING REMARKS

The production and use of frozen foods is likely to continue to increase. New technologies that may be applied in this production include high-pressure processing to achieve more rapid freezing and thawing throughout foods, dehydro-freezing, and use of antifreeze proteins.[119] Techniques that result in optimum quality of frozen foods tend to be those that favor the survival of bacteria, yeasts, and molds. Apart from situations in which specific conditions are used that are known to kill protozoa and other parasites, it is probably appropriate to consider that the best freezing practice, which consists of rapid freezing followed by storage at nonfluctuating, low temperature, has the least effect on microorganisms. It is safest, therefore, to assume that freezing and frozen storage do not necessarily cause a marked decrease in the microbial contamination of food.

The incidence of food poisoning associated with frozen foods is very low compared with the amount of these foods consumed. Nevertheless, in recent years a number of outbreaks associated with frozen foods, in particular with ice cream, have been documented. Some of these outbreaks have been very extensive. The increase in global production and marketing of frozen foods such as vegetables and seafoods could lead to an increase in such outbreaks unless sufficient attention is given to possible sources of contamination. Prevention of food poisoning from frozen foods depends primarily on the manufacturer, whether this is a large company or a small-scale producer or caterer. Purchasers also have a responsibility to follow the instructions of the manufacturer regarding storage and preparation. Because many types of food can be frozen a very short time after production or harvesting, freezing offers a major means of preservation of food while retaining excellent quality.

7.1 INTRODUCTION

Many foods, such as grains, nuts and other seeds, are dry at harvest and if maintained under dry conditions are immune from microbial attack and spoilage. Other foods, of normally high moisture content, have been preserved from prehistoric times by drying with the application of heat from the sun or from fire. The microbiological stability of these foods is not a function of their total moisture content but is related to the proportion of this water that can be utilized for growth by contaminating microorganisms.[185] Water activity (a_w) is generally accepted by microbiologists as the expression of available moisture that best correlates with the growth of microorganisms under conditions of reduced water content.[185] Thus, *Staphylococcus aureus* grew in dried meat at water contents down to 23.3%, in dried milk down to 15.7%, and in dried soup down to 62.5%. The levels of a_w at these very different growth-limiting water contents were 0.88, 0.86, and 0.86, respectively.

The a_w of a food may also be reduced, and its microbial stability enhanced, by the addition of solutes. This most commonly involves the addition of sodium chloride to meats, fish, and vegetables, and of sucrose to fruit and fruit products. As with the drying of foods, the effect is to increase the concentration of solutes within the food. Again,[185] 9 of 13 strains of *S. aureus* grew at a_w levels down to 0.86 in nutrient broth with added NaCl, while 4 of 13 grew only to 0.88. Six of 6 strains grew to 0.88 in the same medium adjusted to a range of a_w with sucrose.

Historically, the earliest foods preserved by reduction of a_w were probably meat or fish dried in the sun or over fires. Prior addition of salt, particularly to fish, gave some insurance against the effects of rain during sun drying. Salting by "pumping" is a common practice in the curing of meats. Grapes and stone fruit are commonly sun dried, while syruping preserves jams and jellies, and production of condensed milk involves both concentration and sucrose addition. Preserved foods of very low a_w include chocolate, noodles, biscuits, crackers, and dried egg, milk, and vegetables. The low a_w levels here are a consequence of the need for very low water contents to maintain organoleptic quality; they are well below those necessary to bestow microbial stability. Many other foods are preserved by combination treatments in which smaller reductions in a_w are combined with microbiologically adverse conditions of pH, temperature, preservative, or other factors. Current consumer demands for reduced salt and reduced energy foods, and for low-fat, high moisture foods where solutes are dissolved in more water, make a_w considerations increasingly significant.[200]

7.2 THE CONCEPT OF WATER ACTIVITY

The water activity (a_w) of a solution is the ratio of the vapor pressure of the solution (p) to the vapor pressure of pure water (p_0) at the same temperature:

$$a_w = p/p_0 \tag{1}$$

As a solution or a food becomes more concentrated, p decreases and a_w falls from near the maximum value of 1.0 for pure water (in the absence of capilliary or adsorptive forces). The a_w of the solution is thus equivalent to the relative humidity of the atmosphere in equilibrium with the solution, normally expressed as a percentage (ERH):

$$\text{ERH}(\%) = a_w \times 100 \tag{2}$$

The osmotic pressure (OP) of a solution, which presupposes the presence of a membrane of appropriate permeability properties, is related to a_w by the expression:

$$\text{OP} = -RT \log_e a_w/\bar{V} \tag{3}$$

where R is the gas constant, T is the absolute temperature, and V is the partial molal volume of water. The partial molal volume of a solute or solvent is the increase in volume produced when 1 mole of that solute is added to an infinite volume of its solution at constant temperature and pressure. For water it is $\sim$18.0 cm^3 mol^{-1}.[21]

The relationship between the concentration of an ideal solution and its vapor pressure is expressed by Raoult's Law in the form:

$$p/p_0 = n^2 / (n^1 + n^2) \tag{4}$$

where n^1 and n^2 are the number of moles of solute and solvent, respectively. Thus, here the vapor pressure of the solution relative to that of pure water is equal to the mole fraction of the solvent. One kg water contains 55.51 moles, so that for a 1 molal aqueous solution of an ideal solute:

$$p/p_0 = n^2 / (n^1 + n^2) = 55.51 / (1 + 55.51) = 0.9823$$

However, the a_w values of 1 molal solutions of sucrose and of NaCl are 0.981 and 0.967, respectively, because the solutions are not ideal. Interactions between molecules and ions reduce the effective number of solute particles, while dissociation increases the number. Experimentally derived factors, molal osmotic coefficients, may be used to compensate for nonideal conditions and to permit calculation of accurate a_w values.[177] Note that concentrations are expressed as molal (m), gram moles of solute per kg of solvent, not as Molar (M), gram moles of solute per liter of solution. A detailed discussion of water status in relation to microbiological systems is available elsewhere.[21] In the food industry, various other expressions of solute concentration are used, some specific to the solute, eg, %(w/w), %(w/v), °Brix, °Baumé, °Salinometer. Table 7-1 shows the relation of such values to a_w. Methods for determination of a_w are discussed in Section 7.10.

In fact, foods, particularly those of low and intermediate moisture, are frequently not in true equilibrium, suggesting that an expression such as a_w derived for an equilibrium situation is inappropriate for application to such foods.[195] However, in terms of the shelf life of the foods, changes in water vapor pressure resulting from this inequilibrium appear generally to be within the experimental error of determining a_w ($\sim \pm 0.01\ a_w$).[35] On the other hand, there are situations in which foods exhibit pronounced gradients in a_w, generally as a consequence of temperature gradients[219] (see Section 7.3.1).

Foods that are not in thermodynamic equilibrium may be in a metastable, amorphous state. These are very sensitive to changes in temperature and moisture content and can exist in either a "glassy" or a "rubbery" state[195] as shown in Figure 7-1. Diffusion of water and solutes would be expected to be greatly impaired by the higher viscosity in the former, which might thus be more inhibitory to microbial growth than foods in the "rubbery" state. It has been suggested[195] that the temperature, T_g, at which transition between glassy and rubbery states occurs is the parameter that can define the microbial stability and safety of foods much more reliably than can a_w. It is clear from studies on the use of various solutes to control a_w in laboratory media that there can be marked solute effects on microbial growth,[41] and that factors other than a_w are sometimes important.[79]

Table 7-1 Concentrations of NaCl and Sucrose at Various Levels of Water Activity (a_w) at 25°C

	NaCl			*Sucrose*

Robinson and R.H. Stokes, *Electrolyte Solutions*, © 1959, Butterworth-Heineman.

To date, there is little experimental evidence to support the proposition that glass transition temperatures predict microbial stability, although the concept that viscosity could play an important role is an attractive one. Certainly, the moisture content of foods can profoundly affect the glass transition temperature.[194] The microbiological evidence that has been presented[195] appears to have been refuted.[34] Further, recalculations of published data on the water relations of microbial growth in terms of glass transitions in food systems did not appear to support the contention that mobility considerations allowed accurate prediction of microbial stability.[35] However, "the use of state diagrams, indicating material physical state, combined with water activity effects on processability and deterioration, increases the validity of food stability and shelf-life predictions."[178]

The anomolous results obtained in microbiological growth experiments, referred to as "specific solute effects" (see Section 7.8), do not appear to be well explained by invoking phase transitions, although these may be important in particular cases. Because many foods are not in thermodynamic equilibrium, a_w is an inappropriate term to apply to them.[167] However, since a "pseudo equilibrium" may exist in such foods (and persist for longer than the shelf life of the food), the "pseudo water activity" that is measured will in many cases be very close to a true thermodynamic equilibrium, a_w.[225] Until a more appropriate title is given to the ratio of the measured water vapor pressure in food, whether in thermodynamic equilibrium or not, to the vapor pressure of pure water, "water activity" will probably continue to be the preferred term in food microbiology.

7.3 WATER ACTIVITY AND THE WATER CONTENT OF FOODS

For foods high in soluble components, accurate estimates of a_w can be made from knowledge of water and solute contents.[35] However, the water activity of a food as a function of its water content is more commonly determined by construction of a water sorption isotherm.[71] This is a graph of a_w against a range of water contents at constant temperature (Figure 7-2). (See Section 7.10 for determination of a_w). Instructions for the standardization of isotherm measurements are given elsewhere.[239] The sorption isotherm is generally sigmoid in shape and three regions may often be identified. In region A, water is strongly absorbed to the food as a monolayer. The water in region B is less strongly held in additional hydrogen bonded layers and in small capillaries. In region C, the water is condensed in larger capillaries or other larger spaces or is free in solution. For math-

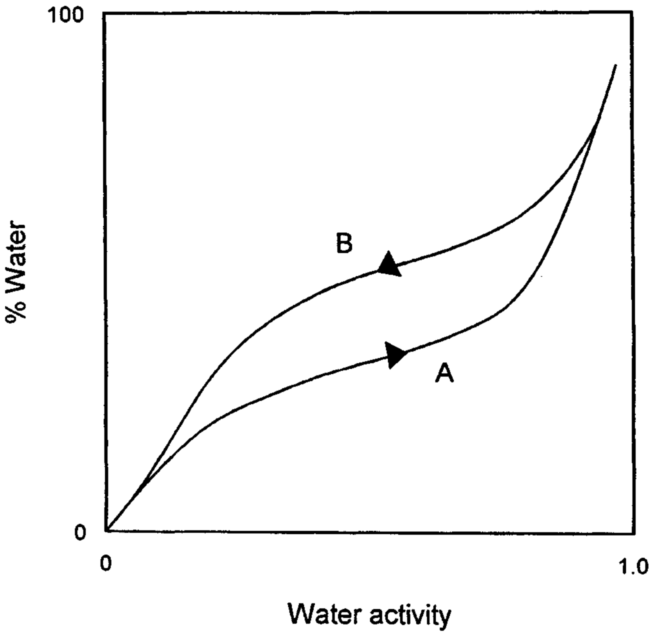

Figure 7-3 Water Sorption Isotherms Showing Hysteresis Loop. Curve **A**, absorption isotherm; curve **B**, desorption isotherm. *Source:* Adapted with permission from T.P. Labuza, Sorption Phenomena in Foods, *Food Technology*, Vol. 22, pp. 262–272, © 1968, Institute of Food Technologists.

ematical models that have been developed to relate a_w to sorbed water, see Rahman.[164]

Isotherms obtained by removal of water from a moist food and by addition of water to a dry food may differ (hysteresis), with water contents in central parts of the desorption curve being higher than in the absorption curve (Figure 7-3).[103,111] No quantitative prediction of hysteresis has been reported.[164] Theories to explain why a much lower vapor pressure is needed to reach a given water content by desorption than by absorption have been based on the structure of the sorbent. They include capillary condensation, partial chemisorption, structural changes in nonrigid solids, and polar sorption in biological materials.[103]

Hysteresis may be expected to have consequences for the microbial stability of foods. However, in foods showing marked hysteresis effects at reduced a_w levels produced by desorption, microbial growth responses were similar to those obtained in laboratory media.[113] When the a_w levels were adjusted by adsorption, inhibition occurred at higher values. These experiments suggest that there is a "fail-safe" aspect to the extrapolation to foods of data obtained in laboratory media. The approximate a_w values of a range of foods are given in Table 7-2. These are in-

Table 7-2 Approximate Water Activity Values for Selected Foods at "Normal" Moisture Contents

Range of a_w	*Foods*
1.00–0.95	Fresh foods (meat, fish, milk, eggs, fruit, vegetables), bread, liver sausage, Bologna sausage, canned fruit in syrup, canned vegetables in brine, low-salt bacon, processed cheese
0.95–0.90	Raw ham, salami, bacon, some hard cheeses, mayonnaise, low-calorie jams
0.90–0.85	Aged hard cheeses, dry ham, fruit juice concentrates, maple syrup (saturated sucrose solution; 0.86 a_w)
0.85–0.80	Sweetened condensed milk, parmesan cheese, fruit cake, high moisture prunes
0.80–0.75	Heavily salted fish, molasses, jams, conserves, marzipan, glacé fruits, prunes, fondants (saturated NaCl solution; 0.75 a_w)
0.75–0.65	Some dried fruit (dates, figs, sultanas) and nuts, dendeng, rolled oats, malt extract
0.65–0.60	Some dried fruits, honey, some confectionery
Below 0.60	Dry pasta, spices, biscuits, crackers, dried milk, dried egg, dried vegetables, flour, instant coffee, cereals

dicative only, as published values vary greatly, because of the large variations in the moisture contents of some foods.

7.3.1 Influence of Temperature

Plots of water content against a_w are termed "isotherms," indicating that all measurements are made at the same temperature. Temperature affects a_w through its influence on water vapor pressure, as indicated in the tables in Resnik and Chirife.[168] The effects are small within the microbial growth range, unless the solution is saturated, when temperature will influence the amount of solute in solution. In a frozen system at equilibrium, the vapor pressures of solid water (as ice crystals) and of the interstitial concentrated solution are identical.[63] Thus, at temperatures below the freezing point of a solution or a food, a_w depends only on temperature.[187] A food at -5°C has an a_w of 0.953, and a food at -20°C has an a_w of 0.823, irrespective of composition.[187] In these cases, a_w is the ratio of the vapor pressure of ice to the vapor pressure of liquid (super cooled) water at the same temperature. Clearly, a_w as well as temperature may have a bearing on microbial growth in foods held at relatively high frozen temperatures.

Temperature gradients within foods can be important where microbiological stability depends on a_w. Water will migrate as water vapor from warmer to colder areas, with consequent increase in a_w in the colder regions. Such migrations may result from diurnal temperature variations and can be of major mycological significance in stored commodities such as grains.[232] Migrations can also be observed within packaged foods in retail chill cabinets where marked temperature gradients may exist, even leading to visible condensation of pure water on food surfaces or the inner surfaces of packaging materials.

7.4 WATER RELATIONS OF MICROBIAL GROWTH

The optimum a_w for the growth of the majority of microorganisms is in the range 0.995–0.980. As a_w is reduced below this optimum, growth rate declines, often linearly; stationary population falls after an a_w range of relative constancy and the duration of the lag phase increases[185] (Figure 7-4). Growth ceases at the a_w where lag becomes infinite. As experiments

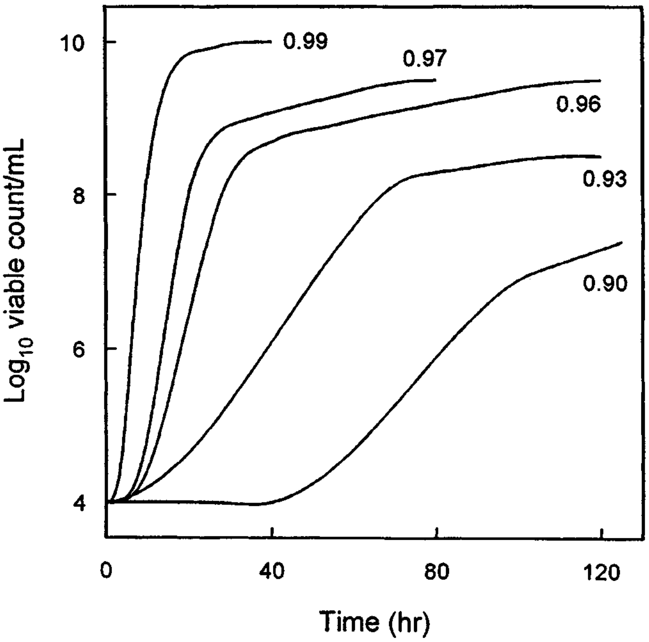

Figure 7-4 Growth Curves of *Staphylococcus aureus* in Laboratory Medium Adjusted to Various Levels of a_w with Hydrolyzed Protein. *Source:* Adapted with permission from J.A. Troller, Effect of Water Activity on Enterotoxin B Production and Growth of *Staphylococcus Aureus*, *Journal of Applied Microbiology*, Vol. 21, pp. 435–439, © 1971, American Society for Microbiology.

are never infinite, the minimum a_w permitting growth is the lowest a_w at which growth was observed during an experiment, and it is therefore important that the duration of such experiments be reported. The most important of these cardinal values, in terms of the microbiological safety and quality of foods, is the minimum a_w for growth. For most bacteria and fungi, growth is confined to the a_w range above 0.90, but in both groups there are organisms of great importance to food preservation and safety that grow at substantially lower levels of a_w. Microorganisms capable of growth below 0.85 a_w are termed xerophiles,[154] and may include groups also described as osmophiles and halophiles. Note that, while both bacteria and fungi have representatives that can grow in highly saline environments, only yeasts and filamentous fungi have strains that can multiply in very high concentrations of sugar. Growth of bacteria and fungi at reduced a_w in specific foods is discussed in Section 7.9.

Most data on the minimum levels of a_w permitting growth of microorganisms are obtained in laboratory media where a_w can be defined to at least 0.002 units.[185] This contrasts with the situation in foods where the accuracy of a_w measurement may be ±0.02 a_w units (see Section 7.10). Accurate comparison of growth limits in media and in foods is therefore difficult.

7.4.1 Bacteria

In general, bacteria grow more rapidly than fungi, so that in conditions favorable to both, bacteria will usually become dominant. The optimum a_w for growth of most species is lower than the a_w of some standard media. Thus, addition of solute to nutrient broth to reduce its a_w from 0.999 to 0.995 will increase the rate of growth of *Escherichia coli* and *Streptococcus faecalis*,[234] *Salmonella oranienburg*,[44] and *Staphylococcus aureus*[185] by about 10%. The a_w of basal brain heart broth is lower at 0.993.[42] Further reduction in a_w results in a decrease in growth rate that is often, but by no means always, linear. This decrease is very steep for organisms with high water requirements and much less so for those capable of growth in physiologically drier conditions. In contrast, the stationary population may remain high until an a_w is reached, which reduces growth rate by half.[185] Lag phase is usually assumed to be shortest where growth is most rapid. This appears to be true in water relations studies. As lag lengthens with reduction in a_w, viability often decreases markedly, eg, by 90%,[75] before multiplication commences, and a very long period may ensue before the original inoculation level is reached.

With spore-forming bacteria, particularly in foods that have received a mild heat treatment, a prerequisite for growth may be spore germination. However, spores of some species may germinate at a_w levels that are too low for outgrowth and growth to proceed. This is true of types A, B, and E of *Clostridium botulinum*[9] and for some *Bacillus* species.[77] However, for *Bacillus cereus*, minimum a_w levels for germination and outgrowth were similar when a_w was adjusted with NaCl.[94]

Traditionally, most emphasis has been placed on the lowering of a_w required to prevent growth of a particular organism. Strangely, this is most often expressed in terms of the lowest a_w permitting growth. The relation of this value to the highest a_w at which growth is completely prevented depends upon the increments of a_w employed in establishing the lower limit. Hence, the lower limit and the level of a_w preventing growth given in the literature are often not very precisely determined. In the practice of food preservation, the a_w required to control growth of a particular microorganism is either determined accurately in the relevant food by a challenge test, or a substantial margin of safety is allowed in utilizing published data.

Table 7-3 shows approximate minimum a_w values for the growth of a range of bacteria of relevance in

Table 7-3 Approximate Minimum Water Activity Values for Growth of Bacteria in Salt-Adjusted Laboratory Medium

Bacteria	*Minimum a_w*	*Reference*
Aeromonas hydrophila	0.97	151
Bacillus cereus	0.93	130
Bacillus stearothermophilus	0.93	41
Campylobacter jejuni	0.98	56
Clostridium botulinum type A	0.94	9
Clostridium botulinum type B	0.94	147
Clostridium botulinum type E	0.97	147
Clostridium perfringens	0.97	101
Escherichia coli	0.95	130
Halobacterium halobium	0.75	24
Lactobacillus helveticus	0.95	182
Listeria monocytogenes	0.92	211
Micrococcus halodenitrificans	0.85	13
Pseudomonas fluorescens	0.97	130
Salmonella species	0.95	44
Staphylococcus aureus	0.86	185
Streptococcus lactis	0.97	182
Vibrio costicola	0.85	13
Vibrio parahaemolyticus	0.95	16

foods. All values were determined with a_w adjusted with NaCl and with other environmental factors, such as temperature and pH, close to optimal for growth. The a_w values have been rounded off to two decimal places, as the methods used to determine a_w are likely to be accurate to ±0.005 a_w units (see Section 7.10). Some generalizations can be made. Pseudomonadaceae have high water requirements, with some strains having lower limits of about 0.97 a_w. Most Enterobacteriaceae, lactic acid bacteria, and clostridia grow down to 0.94 a_w. Some aerobic spore-forming bacteria cease to grow at about 0.90 a_w, with Gram-positive cocci even more resistant to physiological drought. Below about 0.85 a_w, the only bacteria that multiply are halophilic, some of which can grow in media or food saturated with respect to NaCl (0.75 a_w).

Foodborne Bacterial Pathogens

All of the foodborne pathogenic bacteria will grow at a_w of 0.98 or above. This is the range in which are found fresh foods such as fruit, vegetables, meats, fish, and milk. *Campylobacter jejuni* is the most a_w-sensitive foodborne pathogen, with a lower limit of about 0.98 a_w, with growth in 1.5% NaCl but not in 2.0%.[56] As it requires temperatures above 30°C for growth, dies rapidly at 48°C, is microaerophilic, and requires enhanced CO_2 concentration,[204] it could multiply in foods only under quite specific environmental conditions.

More tolerant of reduced a_w are the nonproteolytic (Group II) strains of *Clostridium botulinum* (types E, F, and nonproteolytic B), with a minimum a_w for growth of 0.97 (5% NaCl).[9,132,147] Toxin was produced at all a_w levels at which growth occurred.[147] As the minimum temperature for growth of Group II strains is approximately 3.5°C[184] and their spores are of low heat resistance[85] (see Chapter 41), the greatest hazard of botulism caused by these strains is in inadequately heated, lightly salted foods, particularly fish products (see Chapter 21). Spores of type E are the most commonly isolated *C. botulinum* from both marine and fresh waters and sediments.[85] *Aeromonas hydrophila*[151] and *Pleisomonas shigelloides*[107] are of similar salt tolerance to Group II *C. botulinum.*

The largest group of foodborne pathogenic bacteria has minimum a_w for growth in the range of 0.95 to 0.94. Included are members of the Enterobacteriaceae. Fifteen motile serotypes of *Salmonella* showed very similar water relations for growth in liquid laboratory media, with limiting a_w of 0.95–0.94.[44] A nonmotile strain of *S. enteriditis* was more sensitive. Nonpathogenic[219] and pathogenic[74] *Escherichia coli* also have lower limits of about 0.95 a_w. One of the few halophilic foodborne pathogens is *Vibrio parahaemolyticus*, requiring at least 0.5% NaCl for growth. The minimum a_w for growth in salt-adjusted medium is 0.95.[16] It is a common contaminant of seafoods.

Spore formers are well represented in this group. *Bacillus cereus*, a common contaminant of cereals and milk, grows to a minimum a_w of about 0.95.[163] However, as with other *Bacillus* species, some properties of *B. cereus* are subject to wide variation.[108] Psychrotrophic strains, capable of growth at 5°C, have been isolated from milk,[192] and most of the psychrotrophic strains tested produced the diarrheal enterotoxin.[80] The maximum salt concentration permitting growth of Group I *Clostridium botulinum* types A and proteolytic B was about 10% NaCl (0.94 a_w).[85] However, with a_w adjusted with a three-salt mixture, lower limits for the two types differed, being 0.95 for type A and 0.94 for type B.[147] Toxin was produced at all a_w levels at which growth occurred, although sometimes of low titre.[147] *Clostridium perfringens* also has a lower limit for growth in NaCl-adjusted medium of 0.95 a_w.[101]

Listeria monocytogenes is one of the foodborne pathogens best able to multiply at reduced a_w. Its lower limit is 0.92 a_w in NaCl.[50,152,211] It is also psychrotrophic and ubiquitous, and of particular concern in chilled foods. The only bacterial pathogen with lower water requirement, and the most studied in this context, is *Staphylococcus aureus*. Nine of 13 strains of *S. aureus* grew at a_w levels down to 0.86 in nutrient broth with added NaCl; the other 4 strains grew to 0.88 a_w.[185] The lower limit of 0.86 a_w has been confirmed in extensive studies,[7,61] although growth has been reported at 0.83 a_w.[212] Growth in reconstituted dried foods was also prevented below 0.86 a_w.[185] Although a facultative anaerobe, *S. aureus* grew only down to 0.92 a_w under anaerobic conditions.[185] Enterotoxin A and D production by *S. aureus* occurred at nearly all levels of a_w permitting growth,[61,145] but synthesis of enterotoxins B and C was much more sensitive, being prevented in the a_w range 0.96–0.93.[145,217]

Halophilic Bacteria

In addition to tolerating high levels of salt, and hence growing at low a_w, halophiles are unable to grow at very high a_w. The lowered a_w required for growth must be provided by inorganic salts, with NaCl predominating.[219] The widely studied halophiles have been classed as moderate and extreme.

Moderate halophiles require 0.2–0.5 M NaCl (1.2% to 2.9% w/v) for growth (~0.99–0.98 a_w). They grow optimally at about 1 M NaCl (5.9% w/v) (~0.96 a_w), with growth ceasing at 3.5–4.0 M NaCl (20% to 23% w/v) (~0.85 a_w).[13,110] The extreme, or red obligate, halophiles, which are archaebacteria, include the genera *Halobacterium* and *Halococcus*. Growth requires about 3 M NaCl (17.5% w/v) (~0.88 a_w), is optimal at about 4 M (23% w/v) (0.85 a_w), and continues to saturated salt (0.75 a_w).[24,25,110] Although it does not appear to have been explored, it is possible that growth would proceed at even lower a_w if a suitable medium were devised combining high concentrations of NaCl with other solutes. This is likely because at a_w levels below that necessary to prevent lysis, there was little change in growth rate of extreme halophiles with further addition of NaCl.[33] Similarly, in saturated salt medium, *Halobacterium halobium* multiplied only 25% slower than at its optimal salt concentration.[93] Moderate halophiles have been the major spoilage agents of meat curing brines[196] and the extreme halophiles the bacterial spoilage agents of salted, dried fish.[15] Halophiles grown in high-salt environments lyse readily on dilution,[43] so that hosing contaminated plant and equipment with fresh water gives some measure of control of these organisms.

7.4.2 Fungi

Yeasts and molds are generally found in nature in more acid or drier environments than bacteria. Thus many, but by no means all, are more tolerant of reduced a_w than most bacteria, and lower levels of a_w are required to prevent their growth.[4] Pitt's definition of xerophiles as microorganisms capable of growth under at least one set of environmental conditions at a_w below 0.85 includes those fungi that have been termed osmophiles and halophiles.[154] Most such organisms are fungi. The minimum a_w levels permitting the growth of a range of fungi relevant to foods are shown in Table 7-4.

The lowest a_w at which growth of bacteria has been recorded is 0.75 (saturated NaCl). In contrast, the most xerophilic fungi can grow at 0.62–0.61 a_w in the presence of high concentrations of sugars.[124,155,229] Not only are such organisms growing in remarkably high concentrations of solutes, but the replication of genetic material is taking place close to 0.55 a_w, the a_w at about which DNA becomes disordered.[62] Most of the organisms capable of growth below 0.90 a_w are ascomycetous fungi or conidial fungi.[159]

Table 7-4 Approximate Minimum Water Activity Values for Growth of Food-Related Fungi

Molds	*Minimum a_w*	*Reference*
Aspergillus flavus	0.80	160
Aspergillus ochraceus	0.77	155
Aspergillus parasiticus	0.80	160
Aspergilus penicillioides	0.73	159
Aspergillus restrictus	0.71	198
Botrytis cinerea	0.93	199
Byssochlamys nivea	0.84	150
Chrysosporium fastidium	0.69	155
Chrysosporium xerophilum	0.71	155
Eremascus albus	0.70	186
Eurotium amstelodami	0.70	159
Eurotium chevalieri	0.74	5
Eurotium echinulatum	0.62	199
Eurotium rubrum	0.70	199
Paecilomyces variotii	0.84	155
Penicillium chrysogenum	0.79	155
Penicillium cyclopium	0.82	5
Penicillium expansum	0.83	136
Penicillium islandicum	0.83	5
Penicillium patulum	0.81	150
Penicillium viridicatum	0.81	136
Polypaecilum pisce	0.71	237
Rhizopus stolonifer	0.89	159
Stachybotrys atra	0.94	96
Wallemia sebi	0.69	157
Xeromyces bisporus	0.61	155

Yeasts	*Minimum a_w*	*Reference*
Debaryomyces hansenii	0.84	138
Saccharomyces cerevisiae	0.90	41
Zygosaccharomyces bailii	0.80	161
Zygosaccharomyces rouxii	0.62	229

Of major interest are *Aspergillus flavus* and *A. parasiticus*, producers of aflatoxins. They have very similar water relations.[160] Aflatoxins are the mycotoxins that appear to be of most concern in human diets. These fungi have a predilection for nuts and oilseeds, most importantly peanuts, corn, and cottonseed.[159] While the minimum a_w for growth is about 0.78,[5] aflatoxin was not synthesized in inoculated peanuts at 0.83 a_w.[55] In corn at 30°C, aflatoxin was produced by *A. parasiticus* at 0.87 a_w.[137] A study of *A. flavus* and three related species yielded a model that predicted growth rates at a_w within the tested range of 0.995 to 0.81.[72] All the xerophilic species of *Penicillium* have lower limits for growth close to 0.80 a_w (Table 7-4). No bacteria other than extreme halophiles multiply at this a_w. An important property of many xerophilic *Penicillium* species is that they are also psychrotrophic.[159] They are the most common spoilage molds on fermented sausage and cured meats[119] and the most frequently isolated fungi from wheat in cooler climates.[232]

The large group of xerophilic *Aspergillus* spp. have lower a_w limits for growth in the approximate range 0.78–0.71 (Table 7-4). They are among the most common contaminants of grains, nuts, and spices.[88] *A. restrictus* and *A. penicillioides*, both growing below 0.75 a_w, appear to be pioneer species in the colonization of stored grains (A. Hocking, pers. comm.). The more xerotolerant group described in earlier literature as the *Aspergillus glaucus* group are now recorded as the teleomorph *Eurotium* species. Described as the epitome of food spoilage fungi,[159] members of these genera tolerate, or thrive in, elevated temperatures and reduced a_w. Growing poorly or not at all in basal media of high a_w, *Eurotium* species grow optimally at 0.95–0.94 a_w, with lower limits of 0.74–0.62.[159,186]

The other xerophilic molds listed in Table 7-4 are all important spoilage agents of dried and concentrated foods[1] including fish.[158] Of particular interest is *Xeromyces bisporus*, the most xerophilic microorganism recorded. With a minimum a_w of 0.61,[155] its ability to germinate and grow at low a_w far exceeds that of other xerophilic molds.[157]

The most important genera of xerophilic yeasts with respect to food spoilage and food fermentations are *Debaryomyces, Hansenula, Pichia, Zygosaccharomyces*, and *Torulopsis*.[89] All are reported to contain highly salt-tolerant species,[149] but none multiply below about 0.80 a_w in salted foods whereas bacterial halophiles will multiply at 0.75 a_w in NaCl. This salt-tolerant group includes strains of *Z. rouxii*, which contributes to the flavor of soy sauce,[149] yet other strains of this species are highly sugar tolerant. The lowest a_w recorded for yeast growth was 0.62 for *Z. rouxii* in a fructose syrup and a pear concentrate.[229] Another very important xerophilic yeast is *Z. bailii*, which not only grows at 0.80 a_w but also is highly resistant to preservatives.[161]

A prerequisite for fungal growth is frequently spore germination, with sporulation a consequence of growth. The water relations of these processes may be different from those of growth. Spore germination at low a_w may not be followed by growth, particularly if other environmental factors such as temperature are unfavorable.[5] For a group of xerophilic fungi isolated from salt fish,[226] the minimum a_w for growth was generally 0.02 a_w above that for germination. Germination is thus not a consistently reliable indicator of subsequent growth. The germination time of a fungal spore can be more important to the shelf life of a food than the subsequent rate of mycelial growth.[186] There is less information about the influence of a_w on sporulation, but the formation of different types of spores may show different responses to a_w. *Eurotium* species and *Xeromyces bisporus* can form the anamorphic state at an a_w level lower than that at which the teleomorph is formed.[155] For most species of *Eurotium*, the difference is about 0.02 a_w, but can be as large as 0.09 a_w units. *Xeromyces bisporus* formed cleistothecia and ascospores at a_w down to 0.67, and aleuroconidia down to 0.62 a_w.[155]

7.5 WATER RELATIONS OF MICROBIAL DEATH AND SURVIVAL

While many food processes, including heating, aim at the destruction of microorganisms in foods, others, such as fermentations, depend upon their survival. Water activity can play a major role in both destruction and preservation. Generally, heat resistance, or survival, increases as a_w is reduced from that of water (1.0 a_w). The inactivation rate of single celled organisms is essentially exponential,[206] and the rate of destruction is determined as the decimal reduction time, or *D*-value, being the time in minutes required to destroy 90% of the microbial population.

7.5.1 Bacteria

Bacterial spores provide the clearest evidence that heat resistance increases with decrease in a_w from 1.0 to a maximum in the range 0.4–0.2, and then some decrease as a_w approaches zero.[140] Not only does reduction in a_w from 0.998 to 0.4–0.2 greatly increase heat resistance, it causes the greatest increase in the normally least resistant spores. In systems where a_w was controlled by vapor phase equilibrium, this a_w reduction increased the *D*-value at 110°C for *Clostridium botulinum* type E spores by 10^5-fold. At 0.998 a_w, the difference in *D*-value between the least and most resistant bacterial spores was 10^4-fold, but at 0.4–0.2 a_w this difference had been reduced to 10-fold.[140] There are obvious implications here for the heat processing of low a_w foods.

Similar results (optimal survival near 0.3 a_w) were obtained using water vapor equilibration, and glycerol and LiCl solutions to provide controlled a_w.[84] However, the levels of resistance differed greatly among treatments. At this a_w, the maximum survival of water vapor-adjusted spores of *Bacillus subtilis* was 10 times that in glycerol, which was 10 times that in LiCl.

The most studied vegetative foodborne pathogens in relation to heat resistance and a_w are the salmonellae. Again, resistance increased with decrease in a_w, but the influence of the solute used to adjust a_w

was very marked.[51] Using a series of polyols and sugars to control a_w, it was demonstrated that, while the relationship between log *D*-value and a_w was nonlinear, that between log *D*-value and solute concentration was linear, except when glycerol was the bulk solute. It was speculated from a study of electron micrographs that glycerol, which entered the cell, was more protective against heat than the cell water alone, and that plasmolysis of the cell by other solutes gave even greater protection. When heat-sensitive and heat-resistant strains of salmonellae were heated in broth and in broth plus sucrose, NaCl, or glycerol, the changes in heat resistance could not be directly related to the a_w of the heating menstruum.[8] Clearly, any relationship between survival at high temperatures and a_w is much less obvious than that between growth and a_w. The same is true of survival of irradiation. NaCl, but not sucrose, provided some protection to *Salmonella typhimurium* on irradiated pork and chicken.[214]

It is not only the a_w of the heating menstruum that influences heat resistance. *Listeria monocytogenes* showed greatly increased resistance when permitted to adapt to a lower a_w prior to heating.[49,100] This has particular consequences for the safety of foods in respect of pathogens such as *L. monocytogenes* and *Staphylococcus aureus*, which are capable of growth at relatively low a_w levels.

Survival of microorganisms at moderate, near ambient temperatures is also influenced by a_w. In dried milk, vegetative bacteria survived longest at 0.05–0.20 a_w.[86] Thus, the a_w levels that best retain the organoleptic properties of dried foods are also those at which contaminating bacteria, including pathogens, will survive longest. Survival of bacterial spores in the dried milk was little affected at a_w down to 0.05, but fell substantially at 0.0 a_w.[86] In foods of near neutral pH, maximum survival of both *Staphylococcus aureus* and *Salmonella newport* was recorded at 0.11 a_w in air and 0.0 a_w in vacuum.[45] Salmonellae survived the production of both rubbery and glassy states in gelatin.[18] The a_w in glassy states was 0.45–0.28 and in rubbery states was 0.93–0.96. The cells were unable to multiply but remained viable, even when gelatin sheets were transferred between glassy and rubbery states. Survival was lower at a_w between 0.55 and 0.74.

As the a_w of a frozen food is a function not of the overall solute concentration but of the temperature (see Section 7.3.1), the effects of a_w and temperature on the survival of microorganisms in frozen foods cannot be separated.[187] Survival of bacterial spores was generally very high at any temperature of frozen storage, while *Escherichia coli* died quite rapidly at –2°C but remained viable at –20°C.[83] Thus, as with dried foods, frozen storage under conditions that optimize food quality may maximize survival of bacterial contaminants.

7.5.2 Fungi

The most heat-resistant fungal spores are much less resistant than most bacterial spores, but in some the heat resistance is high enough to cause major problems in processed acidic foods. These do not receive as severe a heating as nonacid products. The ascospores of filamentous fungi are more heat resistant than their conidia,[156] while the ascospores and vegetative cells of yeasts appear to possess heat resistance broadly similar to that of fungal conidia.[162] The most significant fungal spores in heat processed foods are those of *Byssochlamys* spp., with *D*-values in the range 1–12 minutes at 90°C.[14] Ascospores of *Neosartorya fischeri* are almost as heat resistant.[201]

The effect of reduced a_w on fungal spores is qualitatively similar to that on bacterial spores. Ascospores of *Byssochlamys fulva* became more resistant as a_w was reduced from 1.0 toward zero,[126] but even under dry conditions resistance was one or two orders of magnitude less than that of the most heat-resistant bacterial spores.

As noted earlier, a_w at temperatures below the freezing point is a function not of solute concentration but of temperature. Nevertheless, solute concentration can have a marked effect on fungal survival at such temperatures. *Torula* species frozen at –17.8°C in orange juice retained near 100% viability with 40% added sucrose, while viability fell appreciably in its absence.[91] Yeasts suspended in 65° Brix orange concentrate were more tolerant of freezing than cells suspended in 45° Brix concentrate.[139] Many substances produced by fungi under stress appear to provide some protection from freezing. In most cases, these are recognized osmoregulants.[99]

7.5.3 Viruses

The effect of food composition in respect to a_w on the heat resistance of enteroviruses has not been studied extensively, but it is known that some salts substantially increase their heat resistance. Enteroviruses are stabilized by 1 M $MgCl_2$ at 50°C[233]; 2 M NaCl has a similar effect,[183] even though it reduces stability at 37°C and below. Whether these are a_w-related effects is not known. As Norwalk virus is not yet culturable, little is known of its survival characteristics. However, outbreaks traced to the consumption of frozen shellfish indicate that it survives freezing in a high a_w food.

7.6 PHYSIOLOGICAL BASIS OF TOLERANCE TO LOW WATER ACTIVITY

7.6.1 Bacteria

Bacteria that can multiply in a defined minimal medium are more tolerant of reduced a_w when growing in a complex medium. *Salmonella oranienburg* could not grow at a_w below 0.97 in minimal medium unless proline was added.[39] In the presence of proline, other amino acids could be utilized and growth proceeded at 0.96 a_w. Addition of several vitamins permitted growth at 0.95 a_w.[39] Reduced a_w stimulated the uptake of potassium[59] and proline[20] in *Escherichia coli*, and similarly *S. oranienburg* accumulated potassium and proline from the medium when adjusting (osmoregulating) to a reduced a_w environment.[42] Similarly, the concentrations of potassium and amino acids within cells of *Staphylococcus aureus* increased as the a_w of the growth medium decreased.[46] Such accumulated potassium and amino acids were termed *compatible solutes*[22] and were subsequently defined as "solutes which, at high concentrations, allow all essential cell processes to function efficiently."[21] A range of amino acids and related compounds serve as compatible solutes in bacteria, including proline, glutamic acid, α-amino butyric acid,[134] and glycine betaine.[193] Trehalose is involved in osmoregulation in *Salmonella manhattan*[57] and in *Escherichia coli*.[116]

The observation that overproduction of proline by a mutant of *Salmonella typhimurium* enhanced its salt tolerance[52] led to studies of the genetics of osmoregulation. In nonhalophilic bacteria, these studies have mostly involved *Salmonella typhimurium*[28,29,97] and *Escherichia coli*.[127,165,207] The major compatible solutes accumulated, either by synthesis or transport, by the enteric bacteria are betaine, proline, and trehalose.[19] Intracellular potassium glutamate is believed to be a trigger for the induction of the genetic systems involved in osmoregulation.[19]

The extremely halophilic bacteria (*Halobacterium* and *Halococcus*) not only have an impressive tolerance of NaCl, but also have a very high salt requirement for growth.[110] In the absence of sufficient NaCl, the cell wall disaggregates.[115] To grow in this highly saline environment, the cell excludes sodium and concentrates potassium to very high levels as the main compatible solute.[23,47] Consequently, the enzymes of such bacteria are highly tolerant of potassium ions, of sodium ions, or of both, depending upon their disposition inside, outside, or within the cell membrane.[13]

7.6.2 Fungi

Among the microfungi, the osmoregulatory picture is quite different. High concentrations of electrolytes and nitrogenous compounds are not as prominent in foodborne fungi, although the former may be important in the early stages of adaptation to concentrated environments.[21] Trehalose, glycerol, and other acyclic polyols play major roles. The nonxerotolerant yeast, *Saccharomyces cerevisiae*, and the xerotolerant species, *Zygosaccharomyces rouxii*, both accumulate glycerol, but it appears[21] that in *S. cerevisiae* the process is much less energy efficient. Thus, at low levels of a_w, the metabolic balance is disturbed to the extent that growth is no longer possible. In the very salt-tolerant yeast, *Debaryomyces hansenii*, potassium is accumulated in preference to sodium[143] and, also as with halophilic bacteria, its enzymes are unusually tolerant to sodium and potassium.[2] However, the main solute concentrated during its growth at low a_w is again glycerol. Although mannitol is the polyol most commonly occurring in the fungi, its concentration decreases as the a_w is reduced. The solute commonly accumulated to high concentrations during growth of yeasts at low a_w levels is glycerol.[21]

Compatible, osmoregulatory solutes have been much less studied in the filamentous fungi, possibly because accurate estimation of extracellular water and hence of intracellular water and solute concentration is difficult. *Chrysosporium fastidium* and *Penicillium chrysogenum*, both xerophilic fungi, accumulated glycerol to high levels during growth at reduced a_w in glucose-adjusted media, while the latter also accumulated glycerol when a_w was reduced by addition of KCl.[125] The accumulation of internal solutes by four other xerophilic fungi (*Penicillium janczewskii*, *Eurotium chevalieri*, *Xeromyces bisporus*, and *Wallemia sebi*) and by one nonxerophilic fungus (*Penicillium digitatum*) has been studied by natural-abundance ^{13}C nuclear magnetic resonance spectroscopy.[90] All accumulated increasing glycerol concentrations as a_w was reduced in sorbitol- or in glucose/fructose-adjusted media, but when grown in media adjusted with NaCl only *Wallemia sebi* maintained a high internal level of glycerol at 0.85 a_w or below.[90]

In summary,[89] the accumulation of glycerol permits growth below 0.75 a_w, as demonstrated by the xerophilic yeasts and molds. Halophilic bacteria, concentrating potassium, are a special case. Accumulation by nonhalophilic bacteria of betaine, alone or with glutamate or potassium, is associated with growth to about 0.90, while accumulation of proline and/or glutamate allows growth of bacteria to 0.94–0.96 a_w. The genetic control of osmoregulation is better understood in nonhalophilic bacteria and in yeasts than in halophilic bacteria and filamentous fungi.

7.7 INTERACTIONS OF a_w WITH OTHER ENVIRONMENTAL FACTORS

Data on the minimum a_w permitting growth of microorganisms are usually, and correctly, reported for situations where other environmental conditions are close to optimal. However, except in foods of a_w below about 0.70, the use of a_w for preservation will be in combination with other factors, which will themselves usually exert an inhibitory effect. The interactions between these factors are complex and usually appear to be additive.[219] The most important in this context are the other intrinsic factors, pH, Eh, and chemical preservatives, and the extrinsic factors, high and low temperatures and gas atmosphere.[92]

The use of combined inhibitors is important organoleptically. A food preserved solely by high salt or low pH may well not be palatable, but lower salt concentration combined with less acid may be acceptable. Similarly, mild heating of a food of low a_w may give a better textured product than the high heat required to stabilize a food of high a_w.

Much of the research on combination treatments has involved foodborne pathogenic bacteria and xerophilic fungi. Examples of pH and a_w interactions are provided by *Clostridium botulinum*. At 37°C, growth of type A occurred at a_w levels down to 0.94 at pH 7, but at pH 5.3 the lower limit was 0.99.[9] For proteolytic type B at 40°C, the lower limits were 0.94 at pH 7 and 0.96 at pH 6.[147] Two types of temperature effect are illustrated by an osmophilic yeast. Minimum a_w levels for fermentation were 0.66 at 30°C, 0.70 at 20°C, and 0.78 at 10°C.[229] In contrast, multiplication occurred at 40°C only if the a_w was substantially reduced by salt or sugar.[149]

Considerable attention has been paid to meat preservation systems, involving a_w or NaCl, pH, and sodium nitrite. This has stemmed largely from the trend to reduce the levels of salt and nitrite in the diet (see *Meat* under Section 7.9.2). The foodborne bacterial pathogens on which such studies have been reported include *Clostridium botulinum*,[135,175] *C. perfringens*,[75] *Escherichia coli*,[74,209] *Listeria monocytogenes*,[26,58,133] *Salmonella* spp.,[73,74] *Staphylococcus aureus*,[27,210] and *Yersinia enterocolitica*.[17,208]

Classic examples of combined preservation are the intermediate moisture foods (IMF). Definitions of IMF abound, an early description being foods of 0.7 to 0.9 a_w with water contents of 20%–50%.[104] Essentially, the a_w of the food is reduced to a level where pathogenic and most spoilage bacteria will not grow (this a_w may be increased, eg, by reducing pH), and fungi are controlled by chemical mycostats or some other inhibitory factor. The result is a food that is microbiologically stable but sufficiently moist to be consumed without rehydration.[219] As examples, meat products, including fermented sausages, may be preserved by low pH and low a_w alone.[121] Among intermediate moisture (IM) fruits, dried (but moist) apricots are preserved by reduced a_w and the inhibitory effect of residual sulfite applied to control browning.[219] Heat plays a vital role in the preservation of many foods in this category. Commonly this involves a mild heat treatment that inactivates vegetative cells, packaging that prevents recontamination, and levels of a_w, pH, Eh, chilling, preservatives, or other factors that prevent outgrowth of surviving spores.[219] Mathematical modeling of the combined effects of a_w, pH, and Eh on heat destruction of bacteria and yeasts has given good correlation with measured values.[166]

The concept of considering all practical preservation factors together, the level of inhibition or destruction caused by each, and the order in which they are applied, has been developed by Leistner as the "Hurdle Concept."[118,121] Factors most commonly considered in the hurdle concept, besides a_w, have been pH, temperature (high and low), Eh, oxygen tension, modified atmospheres, competitive flora, and a wide range of preservatives.[118] Other potentially useful treatments or components of such systems are pressure, ultrasound, radiation, and microstructure.[118]

Pioneering studies on IMF involved formulation of hennican, a chicken-based adaption of the buffalo meat and berry food prepared by American Indians.[1] The concept was also applied to the formulation of moist pet foods.[102] More recent applications of hurdle technology have involved meat products[117,118] and refinement of traditional Latin American IM foods.[3] In the former, shelf-stable (SS) meat products were classified as F-SSP, a_w-SSP, and pH-SSP, being foods stabilized predominantly by heating, reduced a_w, and reduced pH, respectively.[117]

An example of F-SSP is autoclaved sausage, where the heating (20 to 40 minutes at 103°–108°C) causes sublethal damage to surviving bacterial spores, the

a_w inhibits surviving spores, the Eh inhibits a_w-tolerant *Bacillus* species, and the pH is mildly inhibitory. Residual nitrite (after heating) may contribute to the inhibition. The a_w-SSP are exemplified by Mortadella, where reduced a_w is achieved largely by formulation, and Bruhdauerwurst, where it is achieved largely by drying.[117] With heat treatments to center temperatures of 75°–78°C, surviving bacterial spores are inhibited by an a_w of 0.95.[117] Mold growth on the casings may be controlled by smoking or, more efficiently, by application of sorbic acid.[117] The pH-SSP include brawns, which are acidified to pH 4.5–5.0 with acetic acid, and a Bologna-type sausage acidified to pH 5.4–5.6 with gluconic acid derived by hydrolysis from glucono-delta-lactone added to the formulation. For stability without refrigeration, the latter is reheated and vacuum packed at 80°C for about 1 hour.[117] Clearly, there is considerable overlap between these processes, most of them being dependent to some degree on combinations of heating, reduced a_w, and reduced pH.

In the study of traditional Latin American IM foods, analyses of individual foods and comparisons among similar foods from different regions enabled improvements to be made in stability and organoleptic quality, largely by increasing the range of hurdles employed and by introducing mild heating procedures in many cases.[3]

7.8 SPECIFIC SOLUTE EFFECTS

As noted earlier, the application of the a_w concept to microbial growth in concentrated environments rests on the assumption that the effects observed are solely a function of a_w.[41] However, in some instances, responses at a given a_w differ when different solutes are used to control the a_w value. These have been termed *specific solute effects.*[41] The tolerance of specific solutes by halophilic bacteria and some xerophilic fungi have already been referred to and, in the case of halophiles, explained.[21] Much less dramatic effects can also be of concern. When *Salmonella oranienburg* was grown in a glucose-salts medium, additions of NaCl, sucrose, and a mineral salts mixture produced comparable growth inhibition at all a_w levels tested.[40] Glycerol, however, was much less inhibitory on an a_w basis. Similar responses have been recorded for many bacteria, including other Gram-negative rods, aerobic, and anaerobic spore formers and *Listeria* (Table 7-5).

Such data indicate[69,78] that, in concentrated environments, microbial growth is subjected to solute interactions in addition to a_w, and suggest that other parameters may better describe the relationship between microbial activity and these environments. This picture is complicated by the fact that there are other bacteria, for example, some Gram-positive cocci, to which glycerol is more inhibitory than NaCl on an a_w basis,[130] a fact that has been largely ignored in the discussion of specific solute effects. The most important of these glycerol-sensitive, Gram-positive cocci in foods is *Staphylococcus aureus*. The influence of a range of other organic solutes and of NaCl on *S. aureus* has been studied in some detail. Three facts emerged: (1) as with glycerol, growth was inhibited at higher a_w in ethanol, 1-3 butylene glycol, propylene glycol, and several polyethylene glycols than in NaCl or sucrose,[222,223] (2) cells died rapidly in all of these solutes except NaCl and sucrose,[12] and (3) ethanol, the diols, and the polyethylene glycols adversely affected the integrity of the bacterial cell wall.[12] There was no correlation between the effects of solutions of sucrose, glucose, NaCl, glycerol, or ethanol on *S. aureus* and their influence on viscosity, dielectric constant, or oxygen solubility or diffusivity in solution at the relevant a_w levels.[12] The streptococci did not appear to share with *S. aureus* this sensitivity to glycerol.[182]

Most of the data on specific solute effects relate to differences in minimum a_w levels permitting growth. Equally or more striking differences may be observed in growth rates in the various solutes at a_w levels near the mid-range for growth. *Eurotium amstelodami* grew optimally at 0.96 a_w in several solutes, but the rates of growth were almost twice as high when a_w was controlled by sucrose or glucose as when it was controlled with NaCl or glycerol.[186] *Salmonella oranienburg* had a similar minimum a_w for growth (0.95) whether salts or sucrose were the bulk solutes, but at 0.97, growth was twice as rapid in salts as in sucrose.[44] Studies of nutritional requirements at this a_w suggested that certain nutrients that stimulated growth rate in salt were not utilized in sucrose.[39,41] Major differences in growth rate at such intermediate a_w levels were also observed with *Bacillus subtilis* and *B. stearothermophilus*.[41] These appear to be profitable regions in which to explore specific solute effects.

There is not yet a parameter that will correlate better than a_w with the effects of concentrated solutions on microbial growth. It is difficult to suggest where to seek such a parameter in view of the fact that some bacteria appear, in terms of a_w, to be excessively resistant to glycerol while some are excessively sensitive, if bacterial reactions to NaCl are considered "normal." The data of Marshall et al.[130]

Table 7-5 Influence of Solute on the Minimum Water Activity Permitting Bacterial Growth

Bacteria	*Solute*	*Minimum* a_w	*Reference*
Bacillus cereus	NaCl	0.93	130
	Glycerol	0.92	
Bacillus megaterium	NaCl	0.94	130
	Glycerol	0.92	
Clostridium botulinum type A	NaCl	0.94	9
	Glycerol	0.92	
Escherichia coli	NaCl	0.95	130
	Glycerol	0.94	
Lactobacillus helveticus	NaCl	0.95	182
	Glycerol	0.93	
Listeria monocytogenes	NaCl	0.92	211
	Glycerol	0.90	
Salmonella oranienburg	NaCl	0.95	130
	Glycerol	0.94	
Streptococcus lactis	NaCl	0.97	182
	Glycerol	0.92	
Bacillus subtilis	NaCl	0.90	130
	Glycerol	0.93	
Micrococcus species MR1	NaCl	0.83	130
	Glycerol	0.92	
Staphylococcus albus	NaCl	0.88	130
	Glycerol	0.90	
Staphylococcus aureus	NaCl	0.86	130
	Na acetate	0.86	223
	Sucrose	0.87	41
	Glycerol	0.89	130
	Xylitol	0.93	223
	Erythritol	0.95	223

suggest that two bacteria could exist with identical growth responses to NaCl, but with one being more sensitive to glycerol than to NaCl on an a_w basis and the other less. In fact, *Micrococcus lysodeikticus* and *Listeria monocytogenes* both grow to 0.92 a_w in NaCl medium, but in glycerol-adjusted medium the former grows to 0.93 a_w[130] and the latter to 0.90 a_w.[211] This appears to be a "specific cell response" rather than a "specific solute effect," and one that would presumably be difficult to predict from a knowledge of solution properties. For the present, it seems logical to accept that for practical purposes the effects on microorganisms of those solutes most likely to be added to foods in high concentrations, NaCl and sucrose, are adequately described in terms of a_w.

7.9 PRESERVATION OF FOODS AT REDUCED a_w

Control of a_w, either alone or in combination with other inhibitory factors, is the means of preservation of a wide range of foods against both microbial food spoilage and the growth of pathogenic and toxigenic microorganisms. In some cases, the growth of organisms, selected partly or wholly by reduced a_w, plays a major role in food preservation. When such foods are inadequately processed or stored, spoilage follows a pattern determined largely by the prevailing a_w. The following sections consider only the a_w-dependent microbiological aspects of processes. For detailed descriptions of the other microbiological involvement in food processing, see the relevant commodity chapters.

7.9.1 Plant Foods

Cereals, Nuts, and Legumes

The seeds of all cereal, nut, and legume crops lose moisture during maturation. Most are harvested at a_w levels below those supporting microbial growth. However, some, particularly grains, may be invaded by field fungi on the plant prior to maturity when the a_w is still high ($\geq$ 0.95).[37] Such invasion may result from damage by insect larvae, as in the case of *Aspergillus flavus* infection of corn kernels.[38] As grains mature, fungal growth ceases and slow death follows. However, if the grain remains moist, growth continues and some field fungi may produce mycotoxins.[30] The most xerophilic of the mycotoxigenic molds appears to be *Aspergillus ochraceus*. Its minimum a_w for growth is below 0.76, and for the production of the toxins penicillic acid and ochratoxin is 0.80 and 0.85, respectively.[6] Few of the strains that frequently contaminate grains are toxigenic.

If drying of grains is not sufficiently rapid, or if grains are remoistened, they may be attacked by storage fungi. These are capable of invading kernels at minimum levels of a_w that range from 0.85 for some species to less than 0.70 for others[219] (see Section 7.4.2). These storage fungi are by definition[154] xerophiles. They include species of *Aspergillus, Eurotium, Penicillium, Wallemia,* and *Chrysosporium*[88] (Table 7-4).

The recommendation of water contents for commodities as "alarm," "safe," or "limiting" to ensure that fungal spoilage will not occur can be misleading.[186] The slope of many water sorption isotherms is relatively flat over the range 0.6–0.8 a_w, and in some commodities, a change in water content of only 1% can result in an a_w change of 0.04–0.08. This uncertainty can be compounded if the form of the commodity is not given, as in the case of peanuts, which may be traded as kernels or in shell.[106] Here the water contents of kernels and of peanuts in shell at 0.75 a_w were about 9% and 12%, respectively. Some of these crops, eg, peanuts, are harvested while still moist, with a_w levels above 0.90. Mold attack is very likely unless the crop is dried rapidly to a safe a_w. Of particular concern are the aflatoxigenic species, *Aspergillus flavus* and *A. parasiticus*, which grow at a_w levels down to 0.78. However, aflatoxin was not produced by *A. flavus* in inoculated, mature kernels incubated at 83% RH for 84 days.[55]

The problem of moisture migration in stored grain has already been referred to. Temperature gradients, eg, across silos, result in moisture migration as vapor from warm to cooler regions, resulting in a_w gradients that may permit mold growth in grain even if the average moisture content corresponds to a safe a_w.[232] The a_w of many cereal products, such as crackers, biscuits, and dry pasta, is too low to support microbial growth (Table 7-2). However, *Staphylococcus aureus* can multiply in the early stages of pasta production and can reach hazardous levels if drying is slow.[224]

Vegetables

Many fresh vegetables have high a_w and will spoil readily during extended storage unless refrigerated. For some, especially leafy, green vegetables, a_w cannot be reduced sufficiently to greatly restrict microbial growth without wilting and loss of quality. When vegetables are dried to produce a stable product, the a_w required to minimize organoleptic changes is far below that necessary to inhibit all microbial growth. These a_w levels are in the range 0.35–0.10. Most vegetables enter the drying plant carrying heavy microbial loads, mostly of soil origin. Treatments preparatory to drying will destroy the vast majority of these, ie, the lye treatment of tomatoes and some root vegetables and the blanching or precooking of others.[219] Onions, which are not blanched, can enter the dehydrator heavily contaminated.[227] Potatoes, onions, and peas are the most commonly dehydrated vegetables.

Many vegetable foods are preserved by pickling, a process in which microorganisms growing in the food produce sufficient acid to inhibit the growth of spoilage and pathogenic agents. NaCl is added to select these desirable lactic acid bacteria. It does not specifically inhibit those microorganisms causing spoilage or foodborne disease, but is generally more inhibitory to them than to the lactic acid producers, *Leuconostoc* spp. being the most sensitive of these, with lactobacilli and pediococci showing greater resistance.[146] Single or mixed cultures of lactic acid bacteria and sometimes yeasts may be added as starter cultures. During fermentation, the fermentable carbohydrate is depleted, which limits the growth of acid- and salt-tolerant bacteria and yeasts, while the low pH controls salt-tolerant micrococci.[70]

Common fermentations in which NaCl, and hence reduced a_w, is used as a selective agent are applied to cabbage (to produce sauerkraut), to cucumbers, to olives, and to soybeans (to produce soy sauce) (see Chapter 26). To prepare sauerkraut, shredded cabbage is brined under anaerobic conditions with 2% NaCl, an a_w of 0.988. This low concentration permits growth of *Leuconostoc mesenteroides*, the least salt tolerant of the lactic acid bacteria involved. It is succeeded by *Lactobacillus plantarum* and *L. brevis*.[152] Low temperature fermentation (13°–18°C) permits use of lower salt concentrations (0.987–0.990 a_w), which favor growth of heterofermentative species (*L. brevis, L. mesenteroides*) while also permitting homofermentative activity (*L. plantarum, Pediococcus cerevisiae*). This is said to give the highest quality product.

Cucumbers are pickled in higher initial salt concentrations (5% to 8%; 0.97–0.95 a_w) to inhibit *Leuconostoc mesenteroides*. After one week, the fermentation is complete and salt is added progressively to give a holding brine of about 17% NaCl (0.87 a_w).[60] Olives are first lye treated to hydrolyze the bitter glucoside, oleuropein. Otherwise, the process is similar to the pickling of cucumbers, but with *L. mesenteroides* playing a more important role. In both cucumber and olive fermentations, a potential problem is the growth on the surface of the brine of oxidative film yeasts. These may oxidize lactic acid with increase in pH, permitting growth of coliform bacteria.[60] These yeasts, which include *Debaryomyces* spp., are very tolerant of reduced a_w, and control depends on exclusion of oxygen from the fermentation.

Reduced a_w is important in the second stage of soy sauce production.[149] In the first stage, soy beans or soy beans with wheat flour are inoculated with *Aspergillus oryzae* or *A. soyae*. After about three days incubation at ambient temperature, the mat of molded beans is submerged in a strong brine (18% NaCl; 0.86 a_w). Here, the fungal enzymes continue to act on the mash and salt-tolerant bacteria grow and reduce the pH from 6.0 to below 5.0. The xerophilic yeast, *Zygosaccharomyces rouxii*, multiplies and contributes to the final flavor of the sauce. The whole process takes in excess of one year.[219]

Some other vegetables (eg, green tomatoes, green beans, and corn) may also be preserved by fermentation. However, vegetables that contain insufficient fermentable carbohydrate to support a strong lactic fermentation, and those that soften readily, are more commonly salted in very concentrated brines (0.86–0.75 a_w), which prevent the fermentation.[219]

Fruit

Most fresh fruits are in the acid range (pH 4.5–3.7) and are susceptible to spoilage by lactic acid bacteria, yeasts, and molds. Reduction of a_w by drying or syruping controls the bacteria, but many species of fungi are both xerotolerant and acid tolerant. Hence, fruit preserved solely by drying must have an a_w of 0.65 or below. Sulfur dioxide, in the form of sulfites, is added at high concentrations to control nonenzymic browning in some light-colored fruits.[172] The residual levels of sulfite of 1,000–3,000 ppm will prevent fungal spoilage even at relatively high a_w.[219] The use of preservatives such as sorbic acid also assists in providing microbial stability.

If dried fruits, such as prunes, rehydrate to a_w levels above ~0.68 spoilage may ensue, the most likely agents being xerotolerant *Eurotium* spp. High moisture prunes of 0.94 a_w, intended for consumption without rehydration, are prone to spoilage by *Eurotium* species and by *Xeromyces bisporus*, unless treated with an appropriate antimycotic or heated in a hermetically sealed container.[155] *X. bisporus* may grow at a_w close to 0.60.

Fruit products, such as jams and jellies, are heated for long periods during preparation. This not only destroys vegetative microorganisms, but also lowers a_w by partial inversion of the sucrose present. A final a_w of 0.80 or below is sufficient to prevent growth of surviving organisms, although surface growth of fungi may result from recontamination.[219] Liquid fruit products, such as fruit and juice concentrates, syrups, and cordials, although of low a_w and low pH, are difficult to preserve without heating, chilling, freezing, or the use of chemical preservatives. A pear concentrate, without preservative but of pH 4.5 and 0.62 a_w, supported growth of the xerotolerant yeast *Zygosaccharomyces rouxii*.[229] Both sorbic and benzoic acids should control *Z. rouxii* in acid products at any a_w. However, *Zygosaccharomyces bailii*, a very preservative-resistant yeast, is a common spoilage agent of such products at a_w above 0.80.[161]

Reduced a_w may also play an important role in the microbial stability of canned fruit. These receive a mild heat treatment, primarily because the low pH restricts outgrowth of surviving bacterial spores. However, the reduction in a_w provided by the canning syrup probably makes a synergistic contribution with pH. Growth of the butyric anaerobe *Clostridium pasteurianum* occurred in canned pears in syrup at pH 3.8 if a_w was ≥ 0.985, but not at pH 3.8–4.0 when a_w was 0.985–0.975.[95]

Sugar, Syrups, and Confectionery

Sugar, widely used in food preservation to reduce a_w, does not undergo microbial spoilage in its dry, crystalline state. Storage at high humidity results in surface hydration and formation of a saturated sucrose solution of 0.86 a_w. This a_w is within the growth range of xerophilic fungi, but in the absence of adequate noncarbohydrate nutrients spoilage does not occur. The microorganisms of most importance in sugar are the thermophilic bacterial spores that, when contaminated sugar is used in the formulation of canned foods, can survive the heat process and cause post-processing spoilage.[141]

Liquid sugar, which is either sugar concentrated after the decolorization step in refining or is crystalline refined sugar dissolved in water, has a sugar content of 66°–76° Brix, depending on the extent of inversion.[93] At 66° Brix, the a_w is that of a saturated sucrose solution (0.86), and the syrup can support slow growth of xerophilic yeasts, particularly if a_w gradients occur during storage. "Totally" inverted syrups (72% to 73% solids of which 5% is sucrose) have much lower levels of a_w and much greater stability. The syrups derived from the hydrolyzed starch of corn or other plants have colligative properties similar to sucrose invert sugars of similar concentration. Honey is harvested from the comb at about 0.60 a_w. The main cause of spoilage after some rehydration has been *Zygosaccharomyces rouxii*.[231] The heat treatment that is now given to honey to prevent glucose crystallization effectively sterilizes it.[159]

Confectionery, which includes chocolates, toffees, and candies, is normally resistant to microbial attack as a consequence of a_w levels mostly in the range of 0.65–0.50. Although the low a_w of chocolate precludes microbial growth, it and the high fat content protect vegetative bacteria from destruction by heat during the conching process. Salmonellae surviving in chocolate have been the cause of several disease outbreaks[76] (see Chapters 35 and 45). In some confectionery, the a_w is much higher.[93] Thus, fondants may be in the a_w range 0.84–0.75. When used in soft-centered chocolates, gas-producing *Clostridium* spp. have caused the product to explode.[235] Inverting the fondant with invertase will lower the a_w sufficiently to control these bacteria, but *Zygosaccharomyces rouxii* can also cause this problem and is much less readily inhibited by reducing a_w. Control of this organism demands thorough cleaning of the filling lines.[159]

7.9.2 Animal Foods

Fish

Fresh fish is a highly perishable commodity and a variety of traditional procedures that involve a_w reduction have been developed for preservation (see Chapter 21). These include salting, drying, and smoking. In salting, suitably prepared fish are stacked in layers interspersed with salt. (If the fish has not been gutted, autolysis occurs, a process utilized in the production of fish sauces.) Salt penetrates the tissues and water is withdrawn, diluting the brine. This brine may be drained to give a dry salted product, or permitted to build up until the fish is covered. Lost salt is replaced to maintain near saturation of the brine.[219] The salted fish may be dried and/or smoked.

Heavily salted fish are susceptible to spoilage by the halophilic archaebacteria *Halobacterium* and *Halococcus*, capable of growth in a saturated NaCl environment. Spoilage is proteolytic with pink discoloration. These bacteria are aerobic and unable to multiply below 10°C, so exclusion of air or refrigeration provides control. The most common fungal spoilage agent of salt fish in temperate regions appears to be *Wallemia sebi*, the "dun" mold,[68] which can be controlled by dipping fish in a 1% solution of sorbic acid.[219] In tropical regions, *Polypaecilum pisce* predominates.[158,237]

Fish may be hot (65°–90°C) or cold (20°–45°C) smoked after salting. Smoke constituents aid in the preservation of fish, but most of the preservative action comes from the salting and drying treatments. Very lightly smoked white fish was responsible for an outbreak of type E botulism in the United States (US), although undercooking and poor sanitation were probably more important factors.[219] *Clostridium botulinum* type E did not grow below 0.97 a_w.[9,147] Thus, fish salted to less than 5% will require refrigeration to ensure safety from this pathogen. It multiplied at temperatures close to 3°C in the absence of salt,[184] but at 0.97 a_w growth was prevented at 15°C.[148]

Gutted fish may be salted and held in saturated brine for long periods. Exclusion of air prevents growth of red halophilic bacteria, although slow autolytic changes occur.[219]

Meat

Fresh raw meat has an a_w in excess of 0.99 and is highly perishable unless chilled or frozen.[188] Water activity plays a role in the preservation of chilled meat, as the drying that accompanies initial chilling lowers the surface a_w rapidly. At an air temperature of 2°C under normal abattoir conditions of airspeed, humidity, and initial carcass temperature, the a_w of the lean meat surface fell to 0.76 in 30 minutes and took four hours to rehydrate to 0.95 a_w.[123] As the main spoilage microorganisms of chilled meat are Gram-negative psychrotrophic bacteria such as *Pseudomonas* species with lower limits for growth as high as ~0.97 a_w,[130] substantial inhibition results.

Dried meats (eg, charqui, carne secca, and biltong) are prepared traditionally in many countries by sun drying. The major requirement is that the meat is in well separated thin pieces so that the interior, as well as the surface, dries rapidly enough to limit bacterial growth. *Eurotium* spp. were dominant on South African biltong, followed by *Aspergillus* and *Penicillium* spp.[226] More modern technology provides two common drying techniques. In the first, cooked minced meat is dried in hot air tunnels at temperatures exceeding 50°C.[190] Again, speed of drying is important to prevent bacterial growth in cooler, wetter regions. Alternatively, fresh or cooked meat may be freeze dried, or dried from the frozen state. As microbial growth is not a problem in frozen meat, larger pieces can be dried by this process. Little change in microbial load occurs.[93]

Cured and Fermented Meats

There is a wide variety of cured meats and meat products, especially pork and beef. Modern meat curing practices stem from traditional preservation of red meats with salt contaminated with sodium nitrate (see Chapter 19). While salt was the principal preserving agent, salt-resistant bacteria, chiefly micrococci, reduced nitrate to nitrite that reacted with meat pigments, mainly myoglobin, to yield the insoluble red pigment nitric oxide myoglobin.[92] Heating converted this to the pink nitrosyl haemochrome. Modern curing technologies do not rely on the reduction of nitrate by bacteria but add nitrite with much purer NaCl. In general, about 100–200 ppm sodium nitrite is added to cured products, although in some countries much lower concentrations are permitted.[93]

Cured meats are of three broad types: (1) unheated, cured meats, which generally do not require refrigeration, except for some lightly cured hams, sausages, and bacon, (2) products mildly heated to a center temperature of 65°–75°C, which require refrigeration after heating, and (3) severely heated products, which are shelf stable after heating to 100°–120°C.[92] (See also IMF discussion in Section 7.7.) Curing agents do not have a marked effect on the destruction of microorganisms. However, in unheated products they inhibit the growth of undesirable organisms such as salmonellae. In pasteurized products they help to control growth of heat-resistant vegetative bacteria and, in severely heated cured meats, they inhibit the outgrowth of surviving bacterial spores.[92]

The bacteriostatic effect of nitrite in cured meats is greatly affected by pH. It increases as pH decreases from 7.0 to 5.0 and equates well with the concentration of undissociated nitrous acid.[31] In practice, there is a 5- to 10-fold increase in bacterial inhibition per pH unit as pH is reduced over this range.[174]

The microbiology of cured meats is conveniently considered in terms of high and low a_w products, the dividing a_w being 0.92, equivalent to ~10% salt in water.[93] High a_w cured meats include bacon and raw ham and semi-dry fermented and unfermented sausages. Because of relatively low salt content, all require refrigeration for useful shelf life. Even in these lightly cured products of ~ 0.97 a_w, the Gram-negative bacterial rods that predominate in the microflora of raw meats are inhibited. Spoilage is mainly by lactic acid bacteria, which produce souring and green discoloration.

Sliced, high a_w cured meats, such as ham, are readily contaminated in handling and from slicing machines by *Staphylococcus aureus*, which, being salt tolerant, is favored by reduced a_w. Such ham has been a frequent vector for staphylococcal enterotoxin.[87] Smoking of frankfurters, also of high a_w, may leave micrococci predominant, which will multiply in refrigerated storage.[219]

The emergence of *Listeria monocytogenes* as a foodborne pathogen has focused attention on the presence of this psychrotroph in chilled meats. The study of interactions between pH, a_w, nitrite, and ascorbate on growth rate and lag time of *L. monocytogenes* on vacuum packed, sliced, cooked meats makes possible the prediction of safe shelf lives for these products.[58]

High a_w fermented sausages depend for microbiological stability mainly on the acid produced by lactic acid bacteria and the consequent lowering of pH. If produced without added starter culture, the dominant fermenters are usually lactobacilli such as *Lactobacillus plantarum*.[54] However, pediococci such as *Pediococcus cerevisiae* are the preferred starters for some semi-dry sausages.[53] The ultimate pH of fermented sausage is usually in the range 4.5–5.0.[197]

Low a_w fermented sausages, such as many salamis, are generally not smoked or cooked and are eaten raw. They are subjected to longer drying periods than high a_w sausages. *Lactobacillus plantarum* is again usually the dominant bacterium if starter cultures are not added. *Pediococcus* spp. are desirable starters.[153] However, in both German and Italian salami-type sausages, even if used as a starter, *L. plantarum* did not survive in the fermentation. *Staphylococcus carnosus*, used in both countries as a starter, grew well in the products, which had final a_w values of 0.92/0.93 (German) and 0.88/0.91 (Italian).[128] Dry sausages are frequently coated with molds such as *Penicillium*, *Scopulariopsis*, and *Aspergillus* spp.[119]

Large cuts of meat, such as beef silversides and pork legs and sides, are pumped with curing solutions before being submerged in brine tanks to complete the curing process for corned beef, ham, and bacon, respectively. The curing period for corned beef is much shorter than for pig meats. The brines generally contain over 15% NaCl, being much higher for bacon than for ham.[219] Several moderately halophilic bacteria, including *Micrococcus halodenitrificans* and *Vibrio costicola*, both with lower limits of ~0.86 a_w, can grow in slightly less concentrated brines and cause spoilage.[13]

A detailed description of the manufacture of prosciutto (raw ham) followed the chemical, physical, and microbiological changes during curing.[10] The success of the process, in terms of microbiological safety, could only be explained if the various physicochemical properties were taken to act additively or synergistically, since none, individually, would inhibit pathogenic bacteria with certainty. In ham that was cured but not dried (0.95 a_w), staphylococcal enterotoxin was produced in inoculated samples at ambient temperatures within 7 days.[221] When dry cured to 0.92 a_w, toxin was produced within this period only at temperatures above 20°C. If dry cured to 0.89 a_w, enterotoxin production occurred only at 37°C within seven days.

Concern over decreases in the concentrations of salt and nitrite in the curing of meats has lead to extensive studies on the fate of *Clostridium botulinum* in such products. As with raw hams, the interactions between preservative factors are complex (see Section 7.7). In the control of *C. botulinum*, there is a reciprocal relationship between salt and nitrite. In absence of nitrite, 7% salt was required to prevent growth of vegetative cells of type A (5×10^3 cells ml^{-1}) for three months at 35°C; while with 300 ppm nitrite, total inhibition was obtained with 3% salt.[73,175] Reduced pH will also contribute to the inhibitory action, but, as with NaCl as an agent of a_w reduction, there are organoleptic limits of acceptability, which differ between foods. It has been pointed out[131] that many of the studies of factors in combination (see Section 7.7) are relevant only to the product or conditions tested. A better approach is the development of a database of responses of microorganisms to environmental factors encountered in foods, so that predictions of response under untested or new conditions may be made. This approach, termed *predictive modeling,* is discussed in several sources[11,131,180] (see also Chapter 16).

Dairy Products

The main dairy products preserved wholly or partly by reduced a_w are whole and nonfat dried milk, condensed milk, and a wide variety of cheeses. Spray drying is now the most common milk drying process. The product is about 0.2 a_w, too low to support any microbial growth, but the reconstituted product is as perishable as raw milk. After pasteurization to destroy vegetative bacterial pathogens in the raw milk, it is concentrated to 40% to 50% solids and held in a balance tank. If held there too long at temperatures below 65°C, growth of *Staphylococcus aureus* may occur, favored by the reduced a_w, with the possibility of enterotoxin production. The spraying process dispenses milk droplets into a current of dry air at 150°–260°C.[93] In spite of the high air temperature, some survival of vegetative as well as sporing bacteria occurs.[215] The drying process is thus not a substitute for adequate pasteurization and sanitation. Salmonellae have been a particular problem in dried milks and in related infant foods. They have been introduced into dried milks both through cracks in the metal drying cone and, more commonly, from the environment after drying and during packaging.

Sweetened condensed milk contains concentrated milk and sucrose with an a_w of 0.85–0.89. Mild heating during concentrating effectively pasteurizes the product, but no heating occurs after canning. Fungal contaminants may cause gas production from growth of a xerophilic yeast, *Torulopsis lactiscondensi*[219] or mold colonies (buttons) from growth of *Aspergillus* or *Penicillium* spp. if there is adequate air in the head space.[93]

Cheese is a concentrated form of fermented milk obtained by the coagulation of casein.[93] The many types may be classified as unripened soft cheeses and ripened hard-grating, hard, semi-soft, and soft cheeses; processed cheese and cheese spreads; and whey cheeses.[67] These cheeses vary greatly in moisture content and hence in a_w.

The microbiology of all cheeses begins with the starter culture, which may be any of a range of *Lactobacillus* and *Lactococcus* spp., sometimes also *Propionibacterium* or *Leuconostoc* spp.[93] The major microbiological problem during fermentation is attack by bacteriophage on the starter bacteria, which diminishes lactic acid production. The expulsion of water after coagulation and cutting of the curd reduces water content, but the expelled water carries with it much of the salts and lactose that would reduce a_w.[219] Reduction of a_w is achieved by addition to the curd of 1.5% to 5% NaCl, which also enhances flavor.

The most comprehensive report on the a_w of cheeses in relation to composition and microbiology is from Rüegg and Blanc.[182] Analysis of 19 cheese types gave typical a_w levels ranging from 0.988 (cottage cheese) to 0.917 (Parmesan). The a_w levels in hard cheeses ranged from 0.948–0.972, for semi-soft cheeses from 0.95–0.977, and for soft cheeses about 0.98. The authors point out the changes in a_w that continue during ripening of hard cheeses and the pronounced internal a_w gradients that can still exist after six months aging. The a_w of rinds could be very much lower than in the interior. A later report from the same source[181] included much lower a_w values as typical of hard cheeses, 0.86–0.97. The latter a_w values were in accord with those determined in samples obtained from US supermarkets[219] and for those reported for hard Spanish goats' cheese after 16 weeks ripening, where the range of a_w values was 0.88–0.93.[216] The moisture contents in these cheeses were described as very low, because of low relative humidity in the ripening rooms. The micrococci that grow on the surface of Roquefort cheese, which are partly responsible for the specific aroma of this ewes' milk blue vein cheese, multiplied in 20% NaCl (0.88 a_w), and are clearly well adapted to this environment.[228]

7.10 DETERMINATION OF WATER ACTIVITY

A knowledge of the a_w of a food can be vital in determining its microbiological stability and safety. Raoult's Law, describing the relationship between solute concentration and a_w (see Section 7.2), holds only for ideal solutions and then only at concentrations below 1 molal. For nonideal solutes, such as electrolytes generating two or more ions per molecule, a_w may be calculated using the equation

$$\log_e a_w = -vm\phi/55.51 \qquad (5)$$

where v is the number of ions generated per molecule of solute (and is 1 in the case of nonelectrolytes), m is the molal concentration, and ϕ is the molal osmotic coefficient for which values are recorded in the literature.[219] Many models have been devised for the prediction of the a_w of nonideal solutions, and 11 have been reviewed.[164] The models most used in relation to foodstuffs appear to be those of Roos,[179] and the development from this of Caurie,[32] which can handle solutions with mixed solutes; of Norrish[144] for the nonelectrolyte solutions; and of Grover[82] developed from studies of confectionery solids.

Foods are often very complex mixtures that do not lend themselves to the application of such models. However, foods may be formulated to a desired a_w from a knowledge of their water sorption isotherms (see Figure 7-2), and the production of such isotherms demands measurement of a_w. Many methods of measurement exist, most based on the determination, directly or indirectly, of the relative humidity of the atmosphere in equilibrium with the food sample. The methods used for measurement should be both accurate and reproducible. Other desirable attributes are speed, cost, ease of use, durability, and, in some cases, portability.[219] The most inconvenient factor in measuring a_w by equilibration methods is the often inordinately long time taken to reach equilibrium. This is minimized by keeping the volume of the equilibrating atmosphere, or head space, as small as practicable. Detailed data are available on the a_w of selected saturated salt solutions at 25°C for use in equilibration or calibration,[169] on the equilibrium relative humidity values of selected saturated salt solutions at a range of temperatures,[81] on the a_w of unsaturated solutions of salts and of sulfuric acid solutions,[36,168] and on other properties of water.[164]

The methods of a_w measurement in regular use in food research laboratories are as follows[189]: vapor pressure manometers, simple gravimetric and hygrometric methods, dew point, freezing point, fiber hygrometers, and electric hygrometers.

Extensive reviews of these methods were done by Kress-Rogers[109] and Troller.[218] The report of the most comprehensive interlaboratory testing of methods widely used at the time[205] should be consulted for details on the accuracy and precision of those methods. Other comparisons were done by Fernandez-Salguero et al.[64] Performance criteria for electric hygrometers and dew point instruments were done by Rahman[164] and Troller and Scott.[220] There is a need for instruments to measure a_w in foods at higher temperatures and pressures.[164]

7.10.1 Vapor Pressure Manometers (VPM)

The vapor pressure and hence a_w of a food may be measured by manometric procedures with a precision of ±0.005 a_w below 0.85 a_w, but above this a_w accuracy is lower (±0.02) because of temperature control difficulties.[230] Problems may also be caused at high a_w by condensation.[230] A ground food sample is maintained in the sample chamber at ~ −80°C, while the attached manometer is evacuated. The sample is warmed while one side of the manometer is maintained at near zero pressure. The increase in pressure caused by the vapor pressure of the sample alters the fluid level in the sample arm and the reading taken.[219] Vapor pressure measurements should be sensitive to 0.01 mm Hg.

Advantages of the manometric method include the ability to conveniently carry out multiple vapor pressure determinations on the same sample,[213] which simplifies the construction of water sorption isotherms. The manometers are relatively inexpensive, but can be cumbersome and fragile. The method is inappropriate for use with materials that are respiring or fermenting or that expand excessively under high vacuum. Factors controlling the accuracy of the VPM method are discussed by Lewicki et al.[122] They require absolutely uniform temperatures and a high degree of thermometric accuracy.[219] However, tests involving three laboratories in which results obtained with seven methods (direct measurement by VPM, an isopiestic technique, and several electronic devices) were compared indicated that the VPM method was probably the best and most accurate.[112] Tests with three commercial electronic instruments gave an average of 0.051 a_w units difference from VPM values.[202] It was concluded from these studies that a_w values quoted to three decimal places are of questionable validity. The VPM method is frequently used as the standard with which other methods and devices are compared. However, data from an interlaboratory test of a number of a_w measuring instruments and methods revealed the effects of poor temperature control and insensitivity of the pressure measurement in the use of this method.[205]

7.10.2 Simple Gravimetric and Hygroscopic Methods

A simple method[114] requiring little equipment involves determining by interpolation the a_w at which a sample would not lose or gain water. Food samples, usually four, are weighed and placed in separate relative humidity chambers, each containing a solution of different a_w. After one to two hours, water gain or loss is determined gravimetrically and the change plotted against a_w. The plot intersects the line representing zero moisture change at the a_w of the food. Ideally, two standards will have a_w on each side of the a_w of the sample. Saturated salt solutions are suitable as standards for ranging experiments, but, for the small incremental differences required for more accurate estimations, unsaturated solutions, eg, of sodium chloride,[36] may be more useful. A modified graphical interpolation method has been described.[98]

Isopiestic equilibration[176] is similar to the preceding method but the transfer of water vapor proceeds to constant weight, which may take one or more days. Good temperature control is essential and to minimize temperature differences between samples and standard solutions, these are placed in silver dishes that fit neatly into a copper block. An evacuated desiccator containing the copper block is rocked or rotated in a thermostated waterbath while equilibration proceeds. The water contents of sample and reference solution (usually of a salt) are determined, and the a_w of the equilibrated system is found from standard tables.[177] This is the a_w of the sample at its final water content, not in its initial state of hydration. The method provides accurate data for the construction of water sorption isotherms.

Equilibration of food samples with hygroscopic reference material for which a standard isotherm has been prepared also provides good estimates of a_w, particularly in the high a_w range, above ~0.90. Certain proteins[66] and microcrystalline cellulose[230] have been used as standards. The latter gave results comparable to those obtained with electric hygrometers and better than those from the manometric technique at high a_w.[230]

A modified application of this principle involves equilibrating the sample with about 0.01 g of a hygroscopic liquid (a polyol), measuring the refractive index of the liquid by refractometer, and determining the a_w from an ERH versus RI chart. The polyols used included glycerol, ethylene glycol, and propylene glycol. The method is simple and inexpensive. Readings are very rapid, but equilibration will be slow if the a_w of the polyol is far removed from that of the sample. Interference from volatile contaminants is negligible, and there is no hysteresis. The method lacks sensitivity below 0.30 a_w and equilibration time is excessive above 0.95 a_w.[203] No interlaboratory comparison of this method with others has been reported.

7.10.3 Dew Point Methods

Air may be cooled without change in water content until saturation is reached, when condensation occurs. The temperature at which this occurs is the dew point and it may be determined by observing or detecting condensation on a smooth, cooled surface. The dew point temperature is related to ERH or a_w by reference to psychrometric charts. Using thermoelectric cooling and photodetection cells, accuracies of ± 0.005 a_w are claimed. The determination is rapid,[170,171] but measurements can be affected by an unclean mirror surface and by condensibles that have lower critical temperatures than water. In a_w measurements by four methods on Brie and Camembert cheeses, a dew point hygrometer gave values lower by 0.003–0.004 a_w than either psychrometric or cryoscopic methods and showed greater differences from overall average values.[129] Note, however, that a_w values quoted to three decimal places are considered of questionable validity unless obtained by direct vapor pressure measurements.[112,202]

7.10.4 Freezing Point Depression Methods

The a_w of a solution may be determined from the depression of the freezing point relative to that of pure water. The vapor pressure of ice at various temperatures can be related to the vapor pressure of supercooled water.[219] The method is inexpensive, involving an ice-salt slurry of appropriate temperature and a thermometer with which to monitor the temperature change in the sample solution, held in a glass tube in the slurry. Supercooling of the solution usually precedes ice formation and a rise in temperature to the true freezing point. The method is most suitable for use with solutions,[65] although aqueous extracts and homogenates of solid foods, such as meat, have been used. There are difficulties in predicting a_w at temperatures in the microbiological growth range from data obtained near 0°C.[219]

7.10.5 Fiber Hygrometry Methods

Human hair and some synthetic fibers are hygroscopic and stretch when hydrated. By securing one end of a plastic thread and attaching the other end to a lever, the relative humidity of an atmosphere surrounding the thread can be read from a dial. To determine the a_w of a food, this device, which may include a capillary thermometer for temperature compensation, is incorporated into the lid of a canister in which the sample is held. Equilibration between sample and thread takes about three hours. The instrument should be calibrated weekly against saturated salt solutions. It is inexpensive and widely used for routine examinations in the food industry.[120] It is accurate to ± 0.01 a_w.

7.10.6 Electric Hygrometry Methods

Hygroscopic material in the form of an immobilized salt, usually LiCl, is held in a small chamber with a sample of food. The electrical conductivity of the material, when it and the food are in equilibrium, is related to its degree of hydration and hence to the ERH of the head space and the a_w of the sample.[189] The conductivity is measured and converted to a_w, which is displayed and recorded.

In spite of relatively high cost, electric hygrometers are the most commonly used instruments to measure a_w in both research and process control. The sensors need routine calibration with saturated salts in the a_w range relevant to the foods being examined. A disadvantage is the tendency for sensors to become contaminated with polar compounds such as glycerol, glycols, and volatile amines, which influences results. Filters may be used to absorb these compounds, but equilibration time is extended. Resting at low humidity and recalibration restores accuracy.[164,219]

7.10.7 Microthermometry

A small drop of a reference salt solution on the tip of a thermocouple is brought into contact with the atmosphere in water vapor equilibration with a sample. Depending upon the a_w of the sample, water vapor either evaporates from the drop or condenses onto it, and the temperature of the reference solution either falls or rises. The temperature change is measured by thermocouple and depends upon the difference between sample and reference a_w values. Response is linear from 0.78 to 1.00 a_w. The thermocouple is readily rinsed clean of any pollutants between readings; it has long-term stability, and there is no hysteresis. The accuracy is reported as ±0.0034 at 0.92 a_w and ±0.0053 at 1.00 a_w.[191] Another method based on the psychrometric consequences of water condensation onto a thermocouple has been described.[238]

7.11 MOISTURE DETERMINATION

In the construction of water sorption isotherms, accurate and reproducible determinations of moisture content are essential. A range of direct and indirect techniques for measuring the moisture content of foods has been reviewed.[105] The methods commonly employed in food laboratories involve drying weighed samples to constant weight over a desiccant (phosphorus pentoxide) or in ovens. The latter may be conventional, vacuum, infrared, or microwave. When dry weight is determined to establish the a_w of a sample by reference to a water sorption isotherm, it should be obtained by precisely the same method as that used to construct that isotherm. If time is less important than accuracy, conventional oven drying is recommended.[48] The microwave method is the best substitute for the conventional oven if time is important, but extreme care is necessary to standardize power level and drying time, taking into account the possibility of charring.[48]

7.12 CONCLUDING REMARKS

Drying and reduction of a_w are of major importance in food preservation. The most important contributors to the human diet, the cereal grains, are stabilized by low water content. In addition to preservation, drying of many foods bestows the benefits of greatly reduced mass and volume. Many of the traditional methods of preservation by reduced a_w persist, and important benchmarks appear to have been established: no microbial growth below 0.60 a_w, no mycotoxin production below ~0.80 a_w, no growth of pathogenic bacteria below ~0.85 a_w. How stable these criteria are remains to be seen.

To date, microbiologists have concentrated on a_w as the criterion most appropriate to define the availability to microorganisms of water in foods. It is not ideal, as solute specific effects exist. However, many of these instances of solute specificity are observed in laboratory media with solutes not present in foods at levels of significance to a_w. Attempts to explain these anomalies solely in terms of phase transition criteria have not proven helpful, although such criteria are probably more useful than a_w in defining textural properties of foods. Some as yet undetermined combination of these two approaches might greatly advance understanding of the properties of water in foods.

There is often virtue in reducing dependence on a sole inhibitory or preservative factor in foods and much attention is being given to preservation at higher levels of a_w in combination with such microbiological hurdles as reduced pH, mild heating, refrigeration, and chemical preservatives. Predictive microbiology is accumulating data that will facilitate the safe use of such combination treatments. Research on osmoregulation in microorganisms is defining the physiological and genetic basis for growth at low a_w and this may yield means to interfere with the homeostatic mechanisms involved and so improve the efficacy of reduced a_w preservation systems.

8 Control of pH and Use of Organic Acids

Barbara M. Lund and Trygve Eklund

CHAPTER CONTENTS

8.1 Introduction
8.2 The effect of pH, acidulants, and organic acid preservatives on growth of microorganisms
  8.2.1 Investigation of the effect of pH, acidulants, and preservatives on growth
  8.2.2 The effect of pH on initiation of growth
  8.2.3 The effect of pH on rate of growth and yield
  8.2.4 The effect of acidulants and propionic acid on growth
  8.2.5 The effect of benzoic and sorbic acids on growth
  8.2.6 The effect of parahydroxybenzoates on growth
8.3 The effect of pH, acidulants, and organic acid preservatives on survival and death of microorganisms
8.4 Mechanism of effect of pH, acidulants, and organic acid preservatives
8.5 Factors influencing the effect of pH, acidulants, and organic acid preservatives
8.6 Concluding remarks
References

8.1 INTRODUCTION

The pH of foods influences their susceptibility to microbial growth, and acidification, either by the addition of acids or by fermentation, is used in preservation of many types of food. The approximate pH of a range of foods is shown in Exhibit 8-1.The acidity in meat and poultry is due largely to lactic acid, that of fermented dairy products is due also largely to lactic together with acetic acid and, in the case of a cheese such as Emmentaler, propionic acid. Acids such as malic, citric, and tartaric contribute to the acidity of fruits and vegetables. Acidulants used to reduce the pH of manufactured foods such as soft drinks include inorganic acids such as phosphoric acid. pH values of some acidified drinks are as low as 2. Alkaline pH is not used commercially to preserve foods, although a natural food such as egg white may have a pH of 9 or above, which can contribute to microbiological stability.

The optimum pH for growth of many food-associated microorganisms is in the range 6.5–7.5, but some can multiply in highly acidic conditions (Table 8-1). In general, yeasts and molds show a greater ability than bacteria to grow at acid pH, nevertheless some bacteria cause spoilage of acid foods.

Some acids are added to foods in order to adjust their acidity (acidulants or acidity regulators); others are added not to adjust the acidity but to act as preservatives based on their antimicrobial effect. Strong acids are those that are virtually completely dissociated in dilute aqueous solutions; of these, phosphoric acid is used in foods, mainly in cola-type drinks.[48] The remaining acidulants are weak organic acids, which have a range of strengths that are indicated by their dissociation constants, K_a or by pK_a, which is the negative logarithm of K_a. The weak organic acids that are used as preservatives include benzoic, sorbic, and propionic acids. The esters of hydroxybenzoic acid are also considered in this chapter. Some of the properties and applications of acids and esters that are used in foods are shown in Table 8-2. The concentrations of these compounds that may be added to foods are specified by legislation in many countries, but within these specifications the concentration used may be limited by the effect of the acid on the taste of the food.

The antimicrobial effect of weak organic acids used as acidulants is due partly to their influence on the pH of foods and partly to the specific effect of the

Exhibit 8-1 Approximate pH of a Range of Foods

Product	*pH*
Meat

organic acid itself. This latter effect, and that of benzoic, sorbic, and propionic acids, is due mainly to the undissociated form of the acid. On the basis of the Henderson-Hasselbalch equation:

$$\mathrm{pH} = \mathrm{p}K_a + \log([\mathrm{A}^-]/[\mathrm{HA}])$$

where HA is the acid and the anion A^- is the conjugate base, the percentage of undissociated acid at a given pH can be calculated from the formula:

$$[\mathrm{HA}]\% = 100/(1 + 10^{(\mathrm{pH} - \mathrm{p}K_a)})$$

Weak organic acids are valuable agents in food preservation but many microorganisms are able, in certain conditions, to metabolize subinhibitory concentrations of these acids. This ability may be accompanied by relatively high resistance to the acids. Resistance may also occur in organisms that are not able to metabolize the acid concerned and may be induced by growth in, or exposure to, sublethal concentrations.

The extent of the effect of pH and acidulants on microorganisms in foods may be modified by other components in the food, which may have additive or synergistic effects or, conversely, may protect microorganisms and may also influence the dissociation of organic acids. In foods with a high content of fat the concentration of benzoic and sorbic acids in the aqueous phase, where microorganisms are located, will be reduced because the solubility of the acid in fat is much greater than that in water. The partitioning between the water and fat phases of a food will depend on the pH, the type and amount of fat, and the concentration of other components such as sugars and salts.[101]

Information on the effect of pH and weak organic acids on microorganisms in culture media and in foods has been reviewed extensively.[21,33,98,101] The purpose of this chapter is to highlight main principles underlying the effect of these factors.

8.2 THE EFFECT OF pH, ACIDULANTS, AND ORGANIC ACID PRESERVATIVES ON GROWTH OF MICROORGANISMS

8.2.1 Investigation of the Effect of pH, Acidulants, and Preservatives on Growth

In order to investigate the effect of pH *per se* on microorganisms, in particular on foodborne pathogens, experiments have been done using nutrient media adjusted to the required pH with a strong acid, such as HCl. Because this acid is completely dissoci-

Table 8-1 Approximate pH Range for Growth of Microorganisms Important in Relation to Foods

Microorganism	*Min. pH*	*Opt. pH*	*Max. pH*	*Reference*
Bacteria (most)	4.5	6.5–7.5	9.0	3

Table 8-2 Acids and Esters Used as Acidulants (Acidity Regulators) or As Preservatives in Foods

Acid	*Formula*	*pK_a at 25°C*	*Typical Maximum Use Concentration (mg kg^{-1} or mg l^{-1})*	*Examples of Uses*
Acidulants				
Acetic acid	CH_3COOH	4.76^a	(i) generally permitted (ii) GRAS*	pickles, salad cream
Adipic acid	$HOOC.CH_2.CH_2.COOH$	(1) 4.43^a (2) 5.41^a	(i) 1000–6000 (ii) GRAS**	gel-like desserts, fruit-flavored desserts
Citric acid	$(COOH)CH_2.C(OH)(COOH).CH_2COOH$	(1) 3.13^b (2) 4.76^b (3) 6.40^b	(i) generally permitted (ii) GRAS***	soft drinks, fruit drinks, jams, preserves, processed cheese, canned fruit
Fumaric acid	$HOOC.CH{=}CH.COOH$	(1) 3.03^b (2) 4.54^b	(i) 4000	gel-like desserts, fruit-flavored desserts
Gluconic acid	$HOOC.CH(OH)CH(OH)CH(OH)CH(OH)CH_2OH$	3.6^b	(i) generally permitted	
Lactic acid (DL)	$CH_3.CH(OH).COOH$	3.86^b	(i) generally permitted (ii) GRAS*	salad dressing, soft margarine, soft drinks
Malic acid (DL)	$HOOC.CH(OH).CH_2.COOH$	(1) 3.40^a (2) 5.11^a		sometimes used with citric acid in soft drinks, jams
Succinic acid	$HOOC.CH_2.CH_2.COOH$	(1) 4.16^a (2) 5.61^a	(i) 5000–6000 (ii) GRAS*	desserts, soups, broths
Tartaric acid (L)	$HOOC.CH(OH).CH(OH).COOH.H_2O$	(1) 2.98^b (2) 4.34^b		juice-based drinks, jams
Phosphoric acid	H_3PO_4	(1) 2.16^a (2) 7.21^a (3) 12.32^a	700	cola-type, nonfruit drinks
Preservatives

(i) Examples of limits taken from UK legislation.[82,105] These regulations implement European legislation.[39] Generally permitted means that no maximum level is specified, but the additive may be used in accordance with good manufacturing practice. For further information EC regulations and those for specific countries should be consulted.

(ii) Regulations in US. *GRAS for miscellaneous and general purpose usage, **GRAS when used as a buffer or neutralizing agent not to exceed good manufacturing practices, ***GRAS for miscellaneous and general purpose usage when used in accordance with good manufacturing practices.[23]

ated at pH values above about 2.0, adjustment of the pH with HCl enables the effect of hydrogen ions on microorganisms to be tested without the additional effect of an undissociated acid. In experiments to test the effect of pH, or to test the effect of other inhibitory factors, it is important to provide optimum nutrient conditions if the full extent of the ability of the organism to tolerate the inhibitory factor under investigation is to be determined. For example, tryptone soya medium plus yeast extract and glucose gave shorter lag times and more rapid growth of *Listeria monocytogenes* at pH 4.5 than tryptone phosphate medium.[45] pH influences (1) the probability of growth of microbes, (2) the rate of growth, and (3) survival and rate of death.

Many studies of the effect of pH and of organic acids on the ability of microorganisms to initiate growth use a standard inoculum into tubes or flasks or wells in microwell plates, containing medium adjusted to the required composition. Determinations of minimum inhibitory concentration (MIC) of organic acids and other preservatives are made in this way. Such experiments enable investigation of a wide range of experimental conditions but do not reveal the fact that the proportion of microorganisms in the inoculum that are able to initiate growth in different sets of conditions can differ considerably. Thus the MIC will depend on the number of viable organisms in the inoculum. The MIC does not include a measure of the time required for growth, which is often increased in the presence of an inhibitor; this can be reported as additional information. Thus, the inhibitory effects taking place are only partly analyzed in such experiments.

In the use of microwell plates, technical problems can arise that need to be prevented in order to avoid spurious results. With some types of microwell plate and lid evaporation tends to take place, resulting in concentration of solutes. To avoid this, the plates should be incubated at a very high humidity. Volatile compounds, such as acetic acid, may be lost during incubation for long periods of time. In addition, growth of microorganisms in subinhibitory conditions can result in release of volatile compounds, such as ammonia, that can alter the pH in adjacent wells[11] and so lead to spurious results. Measures need to be taken to avoid such changes.

8.2.2 The Effect of pH on Initiation of Growth

The results of experiments to determine the ability of microorganisms to initiate growth at acid pH depend on the number of the microorganisms in the inoculum. In demonstrating this, it is necessary to ensure that the inoculum itself does not change the pH of the medium. Two factors may contribute to the effect of number of microbes in the inoculum. First, there is a random chance that hydrogen ions or undissociated acid molecules will interact with the microbes. Second, the resistance of microorganisms and their ability to survive and multiply in adverse conditions may show a statistical distribution throughout the population, in which case increasing the number of microbes present will increase the likelihood that some will be present that are able to tolerate a given set of conditions. This is illustrated by experiments to test the ability of proteolytic, Group I *Clostridium botulinum* to multiply in a medium acidified with HCl. In conditions that were otherwise highly favorable, the probability of growth from single vegetative bacteria at pH 6.8 within 3 days at 30°C was 1 (ie, 100%), thus growth could occur from an inoculum of a single bacterium, whereas at pH 4.60–4.61, the probability of growth within 14 days was reduced to about 10^{-6} or 10^{-7}, so that an inoculum of between 10^6 and 10^7 bacteria would be required in order that one bacterium would be present that could initiate growth in these conditions (Figure 8-1).[80]

8.2.3 The Effect of pH on Rate of Growth and Yield

In addition to affecting the initiation of growth, pH also affects lag time and the rate of microbial growth. The effect of pH on the lag time will depend on the previous history of the inoculum, for example, on factors such as the phase of growth of the organism, the growth medium, the pH, and the temperature.[45] The effect of pH on growth rate is illustrated by a study of the growth of nonpathogenic *Escherichia coli* in medium adjusted with HCl to pH values between pH 7.0 and pH 4.0; an approximately linear inverse relationship was found between growth rate and hydrogen ion concentration (Figure 8-2).[94] As the pH is reduced, so the yield of cell mass per unit of substrate used falls, reflecting the increased energy needed to maintain a higher and near-constant cytoplasmic pH (see Section 8-4).

8.2.4 The Effect of Acidulants and Propionic Acid on Growth

Many studies have been made of the effect of acidulants on microbial growth by adjustment of the pH of the culture medium with weak organic acids. For example, in experiments to determine the mini-

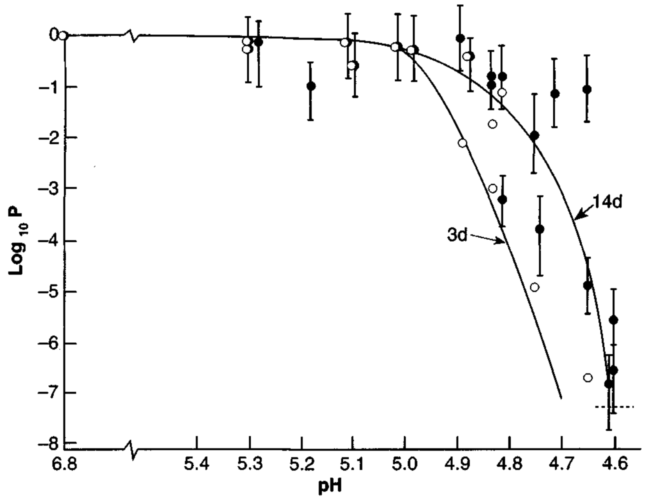

Figure 8-1 Effect of pH on the Probability (*P*) of Growth from Single Vegetative Bacteria of Proteolytic *Clostridium botulinum* ZK3 within 3 Days and 14 Days at 30°C. Continuous lines were predicted from a model based on results for this strain. Symbols represent experimental results for this strain: ○, after incubation for 3 days; ●, after incubation for 14 days. Bars represent 95% confidence limits of log P after 14 days; confidence limits for log P after 3 days were similar but are omitted for reasons of clarity. *Source:* Reprinted with permission from B.M. Lund, A.F. Graham, and J.G. mum pH at which three serotypes of *Salmonella* would initiate growth in a medium adjusted to pH with a range of acids, the order of increase in reported inhibitory effect of these acids was very similar to the order of decrease of their lowest pK_a values (Table 8-3).[22] The concentration of acids required to adjust the pH was not reported.

Although such experiments simulate the practical use of acidulants, they do not allow an analysis of their effect, because they do not separate the influence of pH from that of the organic acid. In addition, the concentration of acidulant needed to adjust a medium or food to a required pH will differ according to the composition and buffering capacity of the medium or food. While an experiment using adjustment of pH with an acidulant will give useful information, the data may not be applicable directly to other media or foods.

In order to separate the effects of pH and of organic acids, the required concentration of the organic acid is added to the culture medium and the pH is adjusted to a specified value, eg, by the addition of HCl

and NaOH or KOH. An example of an experiment of this kind to show the effect of acidulants on initiation of growth of *Yersinia enterocolitica* is shown in Table 8-4. In these conditions up to 2% (w/v) citric acid had no significant effect on the pH at which growth occurred, and on the basis of total concentration, acetic acid was more inhibitory than lactic acid.[12] These experiments were done using microwell plates, with techniques to avoid changes in conditions in wells prior to growth.

Experiments using shaken tubes to study the effect of a series of concentrations of lactic acid adjusted to a specified pH with HCl or NaOH showed that between pH 4 and 7 in the presence of lactic acid, the reduction in growth rate of nonpathogenic *E. coli* was proportional to the concentration of undissociated lactic acid (Figure 8-3). For total lactic acid concentrations of 0–100 mM (ie, up to 0.9% w/v) the reduction of growth rate was equal for equal concentrations of undissociated acid, regardless of the pH or total lactic acid concentration.[94] The authors concluded that under the conditions normally present in foods, that is, at low concentrations of organic acid and low pH, the undissociated acid was the most significant inhibitory factor. However, they concluded that at high concentrations of lactic acid and high pH, the inhibitory effect of the dissociated acid may be significant. For this reason, they included the dissociated acid in the mathematical model that they developed to describe the effects of pH and lactic acid. At temperatures from 10° to 37°C and pH values up to 7.0, the concentrations of undissociated lactic acid that prevented growth were between 5.75 and 8.4 mM.[95]

Similar types of experiments were used to study the effect of acetic and lactic acids on growth of *L. monocytogenes*.[46] The experiments used an optimal culture medium and good aeration, and started with a relatively low inoculum (10^2–10^3 bacteria ml^{-1}). This enabled measurement of the growth rate before changes in the culture medium, due to products of metabolism and limitation of available oxygen, would be sufficient to limit the growth rate. The effects of pH between 4.5 and 7.0 and of total acetic acid or lactic acid concentrations of 2,500 mg l^{-1} and 5,000 mg l^{-1} on the specific growth rate (µ) of *L. monocytogenes* are shown in Figure 8-4. The effect of a specific concentration of acid increased as the pH decreased, ie, the ratio (µ acidulant)/(µ HCl) decreased as the pH decreased, and the effect of acetic acid was greater than that of a similar concentration

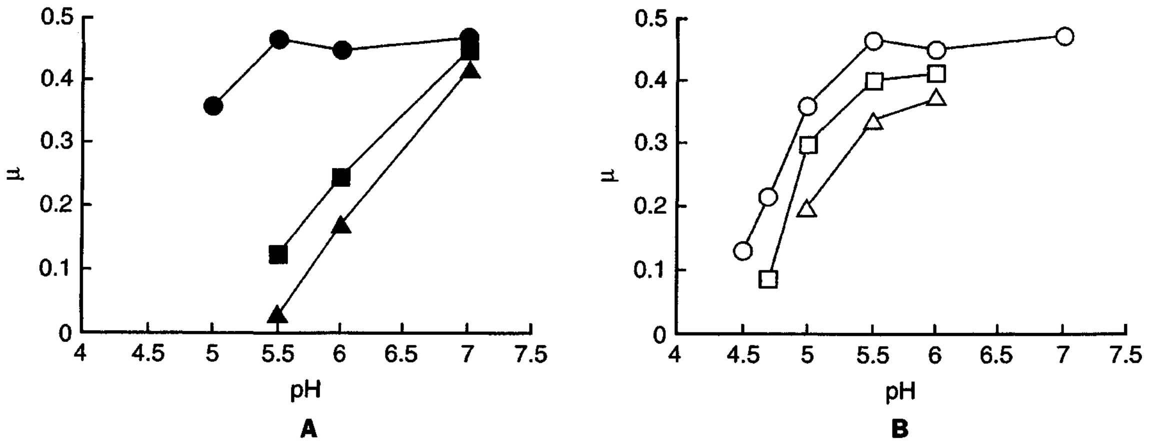

Figure 8-4 (**A**) Effect of pH and Total Acetic Acid on the Specific Growth Rate, μ, of *Listeria monocytogenes* F6861, Serotype 4b at 20°C. ---

of lactic acid. On the basis of the effect of total concentration of acid, expressed as mg l^{-1} (Figure 8-5A) or as mM, on growth rate at pH 5.0, acetic acid had a greater effect than lactic acid, but on the basis of the calculated concentrations of undissociated acid, expressed in mM, limited experiments indicated that the effect of the two acids was similar (Figure 8-5B).

The relative effect of acidulants on different microorganisms may depend on differences in the ability of these microbes to utilize the acids. Of the acidulants that are used widely in foods, acetic acid is usually found to have the greatest antimicrobial effect when assessed on the basis of total concentration, which would be expected from its pK$_a$ value.

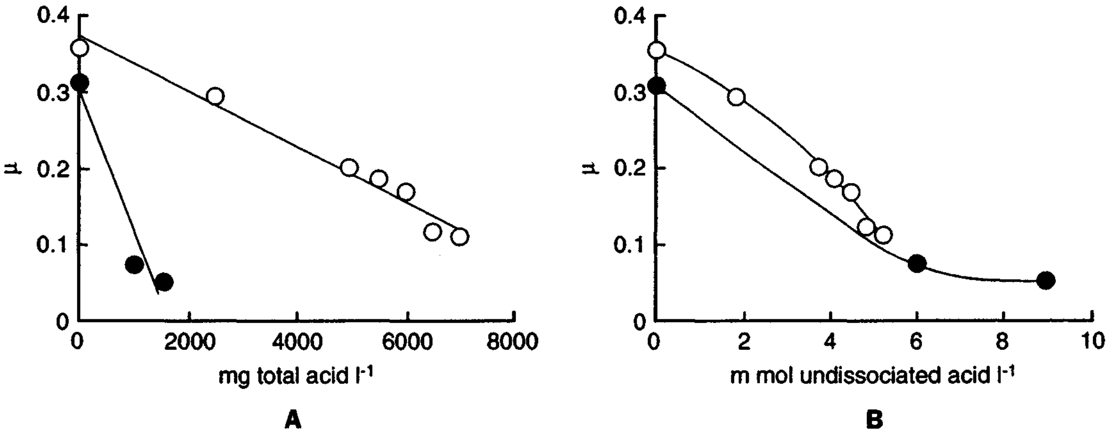

Figure 8-5 (**A**) The Effect of Total Acetic Acid and of Total Lactic Acid, mg l^{-1}, on Specific Growth Rate, μ, of *Listeria monocytogenes* F6861 at pH 5.0 and 20°C. Peck, Predictive Models of the Effect of Temperature, pH and Acetic and Lactic Acid on the Growth of *Listeria Monocytogenes, Food Microbiology,* Vol. 32, pp. 73–90, © 1996, Academic Press, Ltd.

For sensory reasons, the concentration of acetic acid used in foods may be limited, and it may be used in combination with other acidulants such as lactic and citric acid.

Adaptation of *Salmonella* species to growth at lower pH, adjusted with lactic acid, has been reported.[58] Growth on the surface of an agar medium containing a graded concentration of lactic acid, resulting in a pH gradient, reduced the growth-limiting pH for *Salmonella madelia* in a liquid medium, acidified with lactic acid, from 5.2 to 4.6. For other serovars the reduction in growth-limiting pH was about 0.8 units. This increased ability to multiply at acid pH was lost quickly, ie, after two transfers on tryptic soy agar plates.

In experiments described above, acetic acid concentrations of the order of 0.5% caused a marked decrease in the growth rate of *L. monocytogenes* at pH 5.5. In contrast, some bacteria can tolerate much higher concentrations of acetic acid. For example, *Lactobacillus* species can be important in spoilage of acetic acid preserves and *L. fructivorans*, *L. buchneri*, *L. brevis*, and *L. casei* were reported to tolerate acetic acid concentrations of up to 4.2%, 2.5%, 2.5%, and 1% respectively.[29,111] *Lactobacillus fructivorans* caused spoilage of tomato ketchup that had a pH of 3.8 and contained acetic acid and benzoic acid.[7] *Lactobacillus acetotolerans*, isolated from fermented broth of rice vinegar, could multiply in 9% to 11% acetic acid at pH 5.0 and in 4% to 5% acetic acid at pH 3.5.[38]

The yeasts *Saccharomyces acidifaciens* (probably synonymous with *Zygosaccharomyces bailii*[66,113]) and to a lesser extent *Pichia membranifaciens* have been reported as major causes of spoilage of acetic acid preserves in the United Kingdom (UK)[28] and have been reported to tolerate 2.5% to 3.0% acetic acid.[24,111] Yeasts were reported to cause sporadic spoilage of sauces containing at least 1% acetic acid, and 0.7% to 1.0% acetic acid used to preserve tomato sauce was insufficient to give complete inhibition of all spoilage yeasts.[91] Even 2% acetic acid was considered to be inadequate to prevent spoilage of tomato sauce by *Z. bailii* and possibly by *P. membranifaciens*. It was concluded that the stability of the product must depend on aseptic packing and subsequent exclusion of spoilage yeasts.

In the pH range 3.0–3.5, citric, malic, and tartaric acids failed to show an inhibitory effect against spoilage yeasts.[91] *Saccharomyces uvarum*, *Geotrichum candidum*, *Endomycopsis burtonii*, and *Hansenula canadensis* all grew at pH 4.5 with 1% lactate as an energy source but not with 1% propionate as energy source.[83] In the presence of 2% glucose, these yeasts grew at pH 4.5 in the presence of 1% lactate or 1% acetate but not 1% propionate. At acid concentrations up to 400 mM, lactate had less inhibitory effect on growth rate than acetate, but propionate was much more inhibitory than either. As the pK_a values of acetic and propionic acids are similar the greater inhibitory effect of propionic acid indicated a difference between the mode of action of these two acids. This was correlated with utilization by these yeasts of some acetate at low and high concentrations but little or no utilization of propionate.

The mold *Moniliella acetoabutans* was reported as the occasional cause of severe spoilage of acetic acid preserves. It could cause major problems in pickle production, and was sometimes difficult to eradicate once established in a factory.[30,106] If oxygen was available, this mold had been found as the cause of spoilage of products containing >5% acetic acid, but evidence was reported that it could be inhibited by concentrations of sorbic acid that would be suitable for use in foods.[30] *M. acetoabutans* was reported to tolerate 8% to 9% acetic acid at pH 4.0, whereas *Monascus ruber* and *Penicillium glaucum* tolerated 1.8% and 1.4%, respectively.[111]

Acetic acid concentrations of 0.8% to 1.0% at pH 3.5 inhibited *Saccharomyces ellipsoides* and *Penicillium glaucum* and 4% acetic acid was required to give the same effect at pH 7.0.[27] At pH 3.5, 0.2% acetic acid inhibited a wide range of molds involved in the spoilage of bread.[64] At pH 4.5 and pH 5.0, sodium acetate concentrations of 1% and 2%, respectively, completely inhibited growth and aflatoxin production by *Aspergillus parasiticus* at 28°C, whereas concentrations of 0.6% or 0.8% gave partial inhibition and decreased aflatoxin production by 70% and 90%, respectively.[14] A further stain of *A. parasiticus* and six strains of *A. flavus* were inhibited similarly. Propionic acid was more inhibitory, 0.2% at pH 4.5 completely inhibiting growth of three strains of *A. parasiticus*.

Some weak organic acids can have a chelating effect and their antimicrobial activity may depend on the concentration of metal ions present. For example, in a medium adjusted to pH 5.2 with HCl, citric acid concentrations of 10–50 mM (0.2% to 1.0% w/v) inhibited growth from vegetative bacteria and from spores of proteolytic *Clostridium botulinum*, but the inhibition of vegetative bacteria could be prevented and the inhibition of spores reduced by the addition of 12 mM Ca^{2+}.[52] Inhibition of the vegetative bacteria by citric acid could also be prevented by the addition of Mg^{2+} and greatly reduced by Fe^{2+} or Mn^{2+}.

8.2.5 The Effect of Benzoic and Sorbic Acids on Growth

Benzoic acid and sorbic acids are most inhibitory at acid pH; benzoic acid particularly is used mainly to inhibit yeasts and molds in acidic foods. These acids are usually added as their more water-soluble salts, sodium benzoate and potassium sorbate. Several groups of fungi and bacteria, including *Aspergillus niger*, species of *Rhizopus* and *Mucor*, *Pseudomonas putida*, and *Bacillus* species, can metabolize benzoic acid[21]; some strains of the molds *Penicillium*, *Aspergillus*, *Fusarium*, *Mucor*, and *Geotrichum*, and some lactic acid bacteria can degrade sorbic acid.[101]

The reported MICs of benzoic acid at pH 2.6–5.0 against a range of fungi were between 20 and 2,000 mg l^{-1}.[21] Reducing the pH of the culture medium by adjustment with HCl gave a considerable reduction in the amount of potassium sorbate and of potassium benzoate required to inhibit *Aspergillus parasiticus*.[99] At pH 5.5 the maximum concentrations of potassium benzoate and of potassium sorbate that allowed growth were equivalent to 3,048 mg benzoic acid l^{-1} and 1,493 mg sorbic acid l^{-1}, respectively, whereas at pH 4.5 the maximum concentrations allowing growth were equivalent to 762 mg benzoic acid l^{-1} and 373 mg sorbic acid l^{-1}. Whereas some species of fungi do not grow in the presence of 3,000 mg sorbic acid l^{-1} at pH 5.5 and 28°C, others, in particular *Penicillium* species, are more resistant.[71,72] Sorbate-resistant strains of *P. roquefortii* grew at reduced rates in the presence of an initial concentration of up to 9,000 mg sorbic acid l^{-1}. These strains degraded sorbic acid to 1,3 pentadiene, a volatile compound with an unpleasant, kerosene-like odor.[72] In a study of 263 isolates of *Penicillium* spp. isolated from moldy surplus cheese, 57% grew at 25°C and pH 5.5 in medium containing 3,000 mg sorbic acid l^{-1}, 8.8% grew in medium containing 4,500 mg sorbic acid l^{-1}, 0.8% grew in the presence of 6,000 mg sorbic acid l^{-1}, and none grew in the presence of 9,000 mg sorbic acid l^{-1}.[110] In these conditions relatively high concentrations were required to inhibit the *Penicillium* spp., but reduction of the pH and reduction of temperature, conditions applying in many refrigerated foods, would be expected to lower the concentrations of sorbic acid required for inhibition.

The MIC of benzoic acid against a range of yeasts at pH 2.6–5.0 was between 20 and 700 mg l^{-1} but for *Zygosaccharomyces rouxii* and *Z. bailii* at pH 4.8 MICs of 1,000 and 4,500 mg l^{-1}, respectively, have been reported.[21] Resistance of yeasts to benzoic acid was correlated with resistance to sorbic acid[114] (Table 8-5).

Table 8-5 illustrates the difference in sensitivity of yeasts to these acids; it is notable that the strain of *Z. bailii* isolated from a winery was less resistant than the strains isolated from spoiled beverages containing benzoic acid, despite the fact that the inocula for the experiment were grown in the absence of preservative. Growth of *Z. bailii* in the presence of a low level of benzoic acid increased its resistance to this acid.[113] This effect was shown by a series of yeasts, including relatively sensitive strains (Table 8-6).[114] This adaptation of yeasts resulting in resistance to benzoic acid, was correlated with resistance to acetic and propionic acids but not to methyl paraben.[117]

For bacteria at pH 4.3–6.3 reported MICs of benzoic acid are generally between 50 and 3,000 mg l^{-1}, the highest values cited were against *Listeria monocytogenes* and *Lactobacillus* species.[21] In tryptose broth adjusted to pH 5.6 with HCl and incubated at 21°C, 2,000 mg sodium benzoate l^{-1}, equivalent to 1,695 mg benzoic acid l^{-1}, reduced the rate of growth of a strain of *L. monocytogenes* and 2,500 mg sodium benzoate l^{-1} prevented growth.[37] At pH 5.0 and 21°C 2,000 mg sodium benzoate l^{-1} prevented growth and lower concentrations reduced the rate of growth, whereas at pH 5.0 and 13°C 500 mg sodium benzoate l^{-1}, equivalent to 423 mg benzoic acid l^{-1}, prevented growth.

Reported MIC values of sorbic acid for several bacteria and for *Candida albicans* at 37°C, based on experiments in microwell plates, were generally much lower at more acidic pHs; examples of results are shown in Table 8-7.[34] *Staphylococcus aureus* was relatively resistant while *Pseudomonas aeruginosa* was reported to be extremely resistant. In these conditions some of the concentrations of sorbic acid used were much higher than would be used in most foods.

A similar pattern of sensitivity to benzoic acid was reported (Table 8-8).[35] Greater inhibition would be expected at lower temperatures.

Some bacteria are relatively resistant to benzoic and sorbic acid at an acidic pH, including some gluconobacters, which are bacteria that oxidize ethanol to acetic acid. In the case of a representative strain of *Gluconobacter oxydans* that had caused spoilage of a fruit product preserved with sorbic acid, the MICs of sorbic acid and benzoic acid at pH 3.8 and 25°C were 1,000 mg l^{-1} and 900 mg l^{-1}, respectively, and at pH 3.3 were 700 mg l^{-1} and 500 mg l^{-1}, respectively.[40] Growth of the organism in the presence of 400 mg benzoate or sorbate l^{-1} at pH 3.8 resulted in a considerable increase in the MIC and adaptation to increased resistance to sorbate or

Table 8-5 The Effect of Benzoic and Sorbic Acids on Anaerobic Growth of Yeasts at pH 3.5. Inoculum, grown in preservative-free medium, 10^4 cells per 5 ml medium; incubation at 25°C for 1,000 hours. (Sorbic acid, 1 mM = 112 mg l^{-1}; benzoic acid, 1 mM = 122 mg l^{-1}.)

benzoate took place within 1 hour at 25°C. In these conditions, however, *G. oxydans* did not degrade sorbic or benzoic acid at an appreciable rate. *G. oxydans* required highly aerobic conditions for good growth, and elimination of the head space of cultures combined with addition of 400 mg ascorbate and 400 mg sorbic acid l^{-1} to medium at pH 3.8 prevented growth. Sorbic acid–resistant strains of *G. oxydans* isolated from grapes were only slightly inhibited by 1,000 mg sorbic acid l^{-1} in apple juice, pH 3.4.[103]

The concentration of undissociated sorbic acid was correlated with the inhibitory effect of sorbic acid on *Clostridium botulinum*. An undissociated sorbic acid concentration of 28 mg l^{-1} at pH 6.82, equivalent to a total sorbic acid concentration of 3,169 mg l^{-1}, increased the time required for growth at 37°C from spores of three, proteolytic, Group I strains by a factor of between 1.2 and 1.8.[8] At pH 5.65 a total sorbic acid concentration of 2,600 mg l^{-1}, equivalent to an undissociated sorbic acid concentration of 250 mg l^{-1}, increased the time required for growth from an inoculum of about 5×10^4 spores of 10 proteolytic strains by factors of between 2 and 4 compared with the time required in the absence of sorbic acid. A total sorbic acid concentration of 2,000 mg l^{-1} caused little reduction in the probability of growth from vegetative bacteria of proteolytic *C. botulinum* at 30°C and pH 7.0 or 6.0 but at pH values of 5.5–4.9 sorbic acid was much more inhibitory (Table 8-9).[79] At all these pH values, a total sorbic acid concentration sufficient to give about 280 mg undissociated sorbic acid l^{-1} reduced the probability of growth from single vegetative bacteria by a factor greater than 10^4. In initial concentrations of sorbic acid that allowed growth the concentration of sorbic acid became depleted, probably because of degradation by *C. botulinum*. Some other bacteria, particularly lactic acid bacteria, can degrade sorbic acid, producing pungent compounds such as 2,4 hexadien-1-ol and 3,5 hexadien-2-ol.[71]

8.2.6 The Effect of Parahydroxybenzoates on Growth

The pK_a values of parahydroxybenzoates (parabens) are much higher than those of benzoic and sorbic acids (Table 8-2), and at neutral pH parabens have a greater antimicrobial effect than benzoic and sorbic acids against many microorganisms.

Inhibition of molds by parabens has been reported to increase with increase in length of the alkyl chain.[31] A similar effect has been reported against Gram-positive bacteria but has not been observed consistently against Gram-negative bacteria. The concentrations of methyl, ethyl, and propyl parabens required to give total inhibition of a range of fungi, including strains of *Aspergillus niger*, *Penicillium digitatum*, *Saccharomyces cerevisiae*, and *Zygosaccharomyces bailii*, in various conditions of temperature, pH, and time of incubation were between 63 mg l^{-1} and 1,000 mg l^{-1}.[31]

The concentrations required to give total inhibition of a range of Gram-positive and Gram-negative bacteria in various conditions were between 40 mg l^{-1} and 4,000 mg l^{-1}.[31] At pH 6.0 the MICs of methyl paraben against food-associated bacteria were substantially lower than those of sorbic acid, except in the case of *Aeromonas hydrophila*, whereas at pH 5.0 the MICs were similar (Table 8-10).[83] At pH 6.0 and 5°C the growth of these four bacteria was inhibited by paraben concentrations below 1,000 mg l^{-1}, the approximate concentration generally permitted in foods. In the presence of these antimicrobials, the rate of growth of these bacteria was reduced.

Table 8-6 The Effect of Growth of Yeasts in a Subinhibitory Concentration of Benzoic Acid on Resistance to Benzoic Acid at pH 3.5. Inoculum 10^4 yeasts per 250 µl medium. Incubation at 25°C for 6 weeks.

for a prolonged period of time. In the case of foodborne pathogens this may have important consequences for the safety of foods. For example, outbreaks of food poisoning have been attributed to the survival of *Salmonella* spp. in unpasteurized apple cider[17] and in orange juice,[26,86] and by the survival of *E. coli* O157 in unpasteurized apple juice and cider[6,18,19] (see Chapter 27).

Prior exposure of bacteria to low pH can result in increased survival in acid conditions. Because of outbreaks such as those cited above, this effect has been studied particularly in *Salmonella* spp., *E. coli,* and *Shigella.* Different groups of workers have used different experimental conditions to study response to low pH stress, which has resulted in the description of several types of phenomenon.[4]

The term exponential-phase (log-phase) acid tolerance has been described usually on the basis of experiments using cells grown in minimal glucose medium. If cells that are growing rapidly at pH 7.7 are shifted to a pH below 4, they die rapidly. If cells growing rapidly at pH 7.7 are exposed to pH 6 for one generation their ability to survive when exposed to pH 3 increases.This has been termed an inducible acid tolerance response (ATR). Acid tolerance has also been described in stationary-phase cells.[73]

The term acid resistance (AR) has been used in general to describe the results of measurements made on stationary-phase cells (rather than exponential-phase cells) grown in a complex medium and in which survival is measured at about pH 2.5.

The term acid habituation (AH) has been used to describe the response of exponential-phase *E. coli* grown in nutrient broth at pH 5.0. These so-called acid-habituated cells will survive better at pH 3.5 or 3.0 than cells grown at pH 7.0.[50]

The following examples illustrate increased survival of *S. typhimurium, E. coli,* and *L. monocytogenes* on exposure to acid stress. *S. typhimurium* LT2 (an attenuated strain[4]) showed several mechanisms of adaptation to survive exposure to acid con-

ditions including log-phase ATR, a pH-dependent, stationary-phase ATR, and a pH-independent, general stress resistance induced in the stationary phase (AR).[43,67] Cells grown to stationary phase in minimal medium were 1,000-fold more resistant to acid pH than log-phase cells, 1% survived suspension in minimal medium at pH 3.0 for 60 minutes compared with 0.001% of log-phase cells.[67] Stationary-phase cultures with a final pH of 4.3 showed 1% survival after 4 hours at pH 3.0, compared with a survival rate of 0.001% for stationary-phase cultures with a final pH of 7.3.[67] The log-phase ATR appeared to involve two stages: (1) synthesis of a pH homeostasis system, ie, inducible amino acid decarboxylases, and (2) formation of about 50 acid-shock proteins, believed to prevent damage or repair damaged macromolecules. Three regulatory proteins (RpoS, Fur, and PhoP) have been described, each of which controls expression of a distinct set of acid-shock proteins. In a comparison of *S. typhimurium, E. coli,* and *Shigella flexneri* grown in minimal medium, *S. typhimurium* UK1 (a virulent strain) showed stationary-phase ATR that resulted in a 500-fold increase in survival after exposure to pH 3.0 for 4 hours, *S. flexneri* failed to show significant stationary-phase ATR at pH 3.0 while both unadapted and adapted *E. coli* (a toxigenic strain) showed acid resistance[73] (Figure 8-6). *S. typhimurium* UK1 grown to stationary phase in minimal medium also showed a general stress reaction that resulted in acid resistance at pH 3.0 but, in contrast to *E. coli* and *S. flexneri,* after growth in complex or minimal medium did not show acid resistance when exposed to pH 2.5.[73]

Some enterohemorrhagic (EHEC) strains of *E. coli* and some strains of *S. flexneri* grown overnight in complex medium were reported to show acid tolerance (Table 8-11).[5] In the most highly acid-tolerant EHEC strain, this tolerance was greatest in late stationary-phase cells. The acid tolerance was reported not to result from acidification of the overnight culture, the pH of which remained higher than 7.3.

In a study of a range of laboratory and commensal strains of *E. coli* and EHEC strains of O157:H7 the cells were grown in medium (LBG) containing (g l^{-1}) tryptone, 10; yeast extract, 5; NaCl, 5; glucose, 4; the final pH after growth being about 5.[74] After overnight growth, the cells were diluted in LBG medium adjusted to pH 2.0 with HCl and incubated at 37°C. After incubation for 6 hours the percent survival for two laboratory strains was 40% and <0.01%, respectively. The percent survival for three commensal strains was between 47% and 90% and that for 11 EHEC strains was between 6% and 81%. Growth and/or testing in minimal medium resulted in much lower survival, which could be increased by the addition of glutamate or arginine. Evidence was presented that resistance to acid pH could be maintained during storage at 4°C for up to 28 days.

Buchanan and Edelson[15] showed that growth of seven EHEC strains in tryptic soy broth (TSB) supplemented with 10 g glucose l^{-1} for 18 hours at 37°C ensured that the cultures reached a final pH

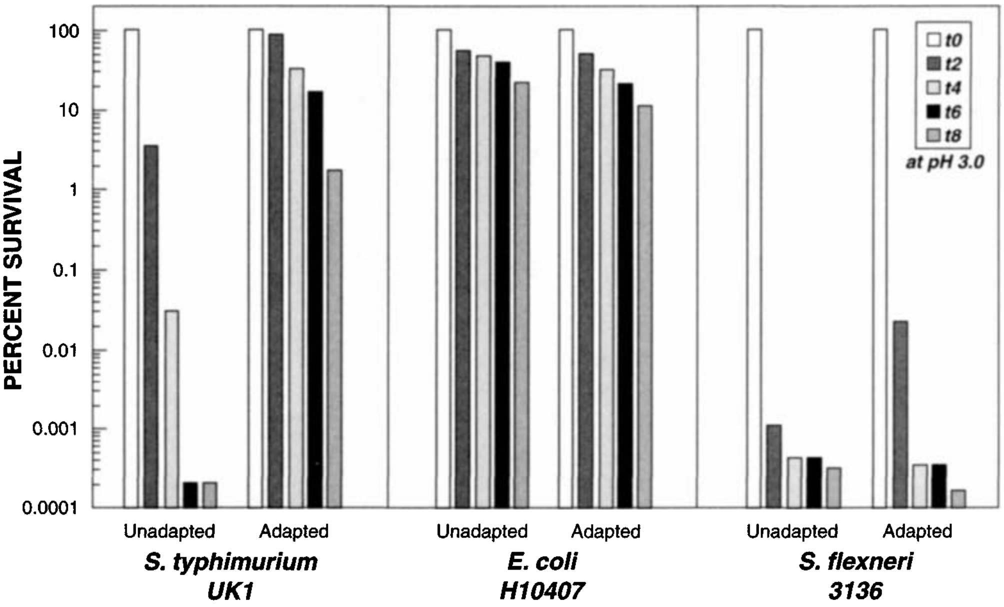

Figure 8-6 Stationary-Phase Acid Tolerance Responses in *Salmonella typhimurium, Escherichia coli,* and *Shigella flexneri.* Cells were grown overnight in minimal glucose medium (pH 7.7), harvested and resuspended to 2 × 10^8 cells ml^{-1} directly at pH 3.0 (unadapted) or to pH 4.3 (adapted) for 2 hours prior to resuspension at pH 3.0. Medium was adjusted to pH 3.0 or 4.3 with HCl. Bars represent average % survival (± 0.5 times the stated value) at 0 to 8 hours after acid challenge. *Source:* Reprinted with permission from J. Lin et al., Comparative Analysis of Extreme Acid Survival in *Salmonella Typhimurium, Shigella Flexneri,* and *Escherichia Coli, Journal of Bacteriology,* Vol. 177, pp. 4097–4104, © 1995, American Society for Microbiology.

between 4.6 and 5.2, resulting in maximum acid resistance. Control cultures in TSB without glucose reached a final pH of 6.9–7.0. Subsequent exposure of the cells to brain heart infusion medium adjusted to pH 2.5 and to pH 3.0 with HCl showed that all seven EHEC strains were acid resistant after growth in TSB plus glucose, ie, at pH 2.5 and 37°C they showed less than a 1.0 log decrease in viable count after 7 hours (Table 8-12). After growth in TSB without glucose there was a considerable difference in the acid tolerance of different strains, ie, at pH 2.5 the log decrease in viable count after 7 hours ranged from <0.3 to >3.8. Four of the EHEC strains were relatively acid sensitive when grown in TSB minus glucose, ie, these strains showed pH-dependent, stationary-phase acid resistance, whereas three of the EHEC strains were acid resistant after growth in TSB with or without glucose, ie, they showed pH-independent, stationary-phase acid resistance. Comparison of the counts on a nonselective medium and on a selective medium indicated that many of the surviving bacteria were sublethally injured and that the proportion of sublethally injured cells was typically greater in glucose-grown cells than in those grown without added glucose. This suggested that resistance to moderately acidic conditions allowed injured cells to remain viable for a longer time.

Exponential-phase cells of *L. monocytogenes* F4642 (Scott A) growing in brain heart infusion medium showed an acid tolerance response that was probably dependent, at least in part, on protein synthesis (Figure 8-7).[32] The ATR was induced optimally between pH 4.8 and 5.2. This bacterium also developed increased acid resistance upon entering the stationary phase; this resistance appeared to be independent of the pH-dependent, exponential-phase acid tolerance and to confer a much greater acid resistance[32] (Figure 8-8).

Response to other stress conditions can increase the acid tolerance of bacteria, for example, heat shock of seven strains of *E. coli* O157 at 48°C for 10 minutes increased the percent of survivors after incubation in a minimal medium at pH 2.5 and 37°C for 6 hours by factors of between 6.5- and 136-fold.[112]

Increased resistance to acid pH can also result in increased resistance to weak organic acids. For example, acid habituation of *E. coli* at pH 5.0 increased survival at pH 3.5 in the presence of lactic acid (31 mM), and acetic, propionic, sorbic, and benzoic acids (12.5 mM).[51] Exponential-phase ATR reduced the sensitivity of *S. typhimurium* to acetic, butyric, and propionic acids at pH 4.4, and stationary-phase ATR reduced the sensitivity to acetic and propionic acids (150 mM acetate or 100 mM propionate) but not to

Table 8-11 Acid Tolerance of Strains of Enterohemorrhagic *Escherichia coli* and *Shigella flexneri*. Fresh overnight cultures in Luria broth (LB) pH 7.3 were diluted 1:1,000 in LB adjusted to pH 2.5 and 3.0 with HCl and incubated at 37°C for 2 hours.

Edelson, Culturing Enterohemorrhagic *Escherichia Coli* in the Presence and Absence of Glucose as a Simple Means of Evaluating Acid Tolerance of Stationary-Phase Cells, *Applied and Environmental Microbiology*, Vol. 62, pp. 4009–4013, © 1996, American Society for Microbiology.

benzoic acid (10 mM benzoate).[2] Conversely, exposure of *E. coli* grown in complex medium at pH 6.5 to 0.1% butyrate or propionate for 1 hour before incubation in medium adjusted to pH 3.5 with HCl for 30 minutes resulted in an increase in survival of between 50- and 200-fold compared with that of cells grown at pH 6.5 without exposure to the weak acid.[54]

A strain of *E. coli* O157 multiplied in a complex medium at pH 7 incubated at 10°C, but not in the medium acidified to pH values between 4.0 and 5.2 with acetic, citric, lactic, malic, mandelic, or tartaric acid (between 1 and 8 mM).[25] At 10°C inactivation occurred at greater rates in the presence of citric, malic, or mandelic acid than in the presence of acetic or lactic acid. At 4°C and pH values between 4.0 and 5.2, survival for periods of 7 to 56 days was greater in the presence of organic acids (eg, acetic acid, 27 mM) than in medium at pH 7.0 without added organic acids.[25]

Survival of stationary-phase *L. monocytogenes* at low pH was reduced by the presence of acetic or lactic acid.[47] Total acetic acid concentrations of 5,000–10,000 mg l^{-1} at pH 3.5, equivalent to undissociated acetic acid concentrations of 79–158 mM, caused a considerable increase in the death rate at 20°C; 10,000 mg total acetic acid l^{-1} causing a decrease by about 10^4 in the number of viable bacteria in four days (Figure 8-9).

Acetic acid has been used as a means of inactivation of Enterobacteriaceae, in particular *Salmonella* spp., in sauces, the criterion being three decimal reductions of *Escherichia coli* in 72 hours at 20°C for sauces with a pH between 3.0 and 4.5 to give a product that is intrinsically safe.[24] The concentrations of salt and sugar present would also influence the death rate. Sauces of this kind are liable to taste strongly acidic or salty and now tend to have been superceded by milder, less acidic products containing additional preservatives (see Chapter 30).

It is evident that the prehistory of microorganisms, including the growth conditions, and the conditions of exposure to acid pH can have a profound effect on survival at low pH. This must be taken into account in any consideration of the ability of pathogenic bacteria and other microorganisms to survive in foods. Methods such as that described by Buchanan and Edelson,[15] to ensure that bacteria show maximum acid resistance, need to be used in experimental work designed to assess the ability of bacteria to survive in acidic

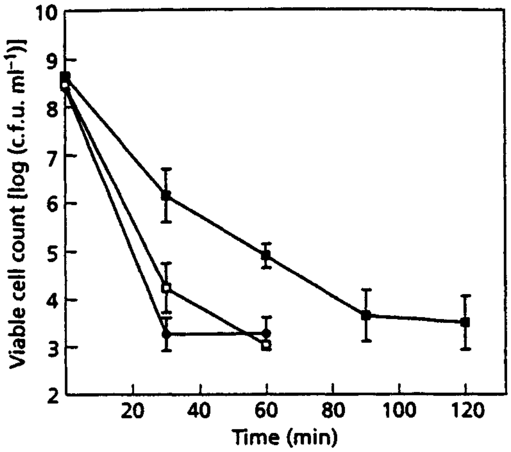

Figure 8-7 The Acid Tolerance Response of *Listeria monocytogenes* Scott A. Cultures were grown to exponential phase (~ 10^8 cfu ml^{-1}) and either preadapted for 1 hour at pH 5.8, ■; left untreated, ●; or preadapted in the presence of 100 μg chloramphenicol ml^{-1}, ☐. (The chloramphenicol was added 15 minutes prior to reducing the pH to 5.8.) The pH of each culture was then reduced to pH 3.0 with HCl and cell viability measured at the time intervals shown. *Source:* Reprinted with permission from M.J. Davis, P.J. Coote, and C.P. O'Byrne, Acid Tolerance in *Listeria Monocytogenes:* The Adaptive Acid Tolerance Response (ATR) and Growth-Phase-Dependent Acid Resistance, *Microbiology,* Vol. 142, pp. 2975–2982, © 1996, Society for General Microbiology.

foods. Acid-adapted *E. coli* O157:H7 (grown in medium adjusted to pH 5.0 with HCl) survived better than nonadapted cells in buffer adjusted to pH 3.85 with 125 mM lactic acid, and also survived better during sausage fermentation by lactobacilli, in hard salami, and in apple cider at pH 3.46.[69] After growth in sterilized orange juice at pH 5.0, four species of *Salmonella* survived at 4°C without a decrease in numbers for 0.21 days, 2.44 days, 4.23 days, and 11.02 days in orange juice adjusted to pH 3.5, 3.8, 4.1, and 4.4, respectively, with citric acid.[88] In addition to the above factors, the possibility of previous exposure of microorganisms to subinhibitory concentrations of weak organic acids should be considered in assessing the preservative effect of these acids in foods.

8.4 MECHANISM OF EFFECT OF pH, ACIDULANTS, AND ORGANIC ACID PRESERVATIVES

Acidulants exert their antimicrobial effect in foods partly by reducing the pH of the food in contact with microorganisms and partly due to the specific properties of the acid. In studies of the mechanism of action of antimicrobials the most significant effects are those that occur at concentrations similar to those that reduce the rate of growth and approach the MICs. Sorbic acid has been reported to affect cell morphology and hydrophobicity and to inhibit spore germination.[101] Both sorbic and benzoic acids have been shown to inhibit a range of enzymes.[21,101] In order to understand the extent to which these effects are the primary cause of inhibition or lethality, it is necessary to consider the relative concentrations necessary for these effects. Studies of bacteria and of yeasts have indicated that uptake of weak organic acids and the influence of the protons and anions within the cytoplasm are a primary cause of inhibition.[33,100]

The permeability of microbial cell membranes to protons is low, so that passive influx of protons from the external medium into the microbial cell is probably limited. The changes measured in the internal pH (pH_i) of microorganisms caused by changes in external pH (pH_o) are generally relatively small, and the cytoplasm tends to be maintained at a pH near to neutrality.[9,56] Maintenance of the internal pH results

partly from the very low permeability of the cell membrane to protons and partly from the buffering capacity of the cytoplasm. Active pH homeostatis in neutrophilic and acidophilic bacteria depends on expulsion of protons through the cell membrane and a corresponding movement of potassium ions into the cell.[56] Extreme lowering of the external pH is liable to cause some decrease in internal pH; eventually the difference between the internal and external pH, Δ pH, reaches a maximum, Δ pH begins to collapse, and the cells begin to die.

The undissociated form of lipophilic acids, due to lack of charge and to hydrophobicity, is able to diffuse through the cell membrane of microorganisms,[55,116] and on entering the cell, where the pH is usually higher than that of the external environment, some of the acid dissociates tending to cause accumulation of protons and preservative anions in the cell cytoplasm. An investigation of the effect of propionic, benzoic, and sorbic acids on *E. coli* indicated that their inhibitory effect was due predominantly to the undissociated acid.[100] There was evidence that inhibition of growth resulted from two effects: (1) a specific inhibition of an unidentified metabolic function by the accumulation of undissociated acid, and (2) a generalized inhibition caused by acidification of the cytoplasm. In the case of propionic, benzoic, and sorbic acids, the former, specific effect was greater. The fact that the molar concentration of sorbic acid required to inhibit *Saccharomyces cerevisiae* was 1/30 that of acetic acid, with a similar pK_a, is further evidence of a specific effect of these acids.[107]

The mechanism for export of metabolically produced organic acids has been studied particularly in lactic acid bacteria.[1] *Lactobacillus helveticus* produces large quantities of lactic acid, which can lower the pH of the external medium to about 3.5; this bacterium has a carrier-mediated system that enables export of undissociated lactic acid or of the lactate anion in symport with one proton.[44]

It has been estimated that MICs for undissociated forms of these weak acids are between 10-fold and 600-fold greater than those of the dissociated forms (Table 8-13).

Strains of *Zygosaccharomyces bailii* are relatively resistant to preservatives and are a major cause of spoilage of acidic foods. Growth of *Z. bailii* and many other species of yeast in the presence of benzoate or sorbate induced increased resistance to these antimicrobials.[113–116] The cells were permeable to the undissociated form of these acids and evidence was reported that increased resistance to these preservatives in many yeasts resulted primarily from an inducible, energy-requiring system that trans-

Table 8-13 Experimentally Determined Values for MICs of Undissociated and Dissociated Organic Acids

Organism	*Acid*	*MIC_u*[a]	*MIC_d*[b]	*Reference*

ported the preservative anion out of the cell. Growth in the presence of low concentrations of preservative stimulated fermentation and resulted in reduced growth yields and reduced growth rates. This was attributable to the increased energy required to maintain the intracellular pH by exporting protons, and to transport the preservative anion out of the cell.[114–116,120] The cell membrane of *Z. bailii* had a relatively low permeability to benzoic acid, and growth in the presence of benzoic acid resulted in a further reduction in the permeability of the cell to benzoic acid and, to a lesser extent, to propionic acid.[118] For a range of 23 yeasts, a correlation was found between the MIC of propionic and benzoic acids and the reciprocal of rate of uptake and the reciprocal of the permeability of the cell membrane to propionic acid, indicating that resistance of yeasts to these acids was associated with relatively low permeability of the cell membrane to these compounds.[119] Growth of *Z. bailii* in the presence of glucose and low concentrations of benzoic acid resulted in stimulation of fermentation and only low concentrations of benzoate were accumulated in the cytoplasm.[120] At higher concentrations of benzoate, near to the MIC, fermentation was inhibited leading to inhibition of growth. This was correlated with an increase in the internal concentration of benzoate, and pH_i was lowered by less than one pH unit to about pH 6.4, remaining much higher than that of the external medium, pH 3.5.[120] A study of the effect of increasing concentrations of benzoic acid on glycolysis reactions suggested that limitation of ATP was an important factor in the inhibition. The presence of benzoic acid resulted in a similar response of *Saccharomyces cerevisiae*, concentrations near to the MIC resulted in a decrease in pH_i of about one pH unit to approximately pH 5.8, compared with pH 3.5 in the culture medium; in contrast to *Z. bailii*, the levels of hexosephosphates were lowered.[121]

Concentrations of sorbic acid that reduced the growth rate of *S. cerevisiae* caused little reduction of internal pH, which remained at between pH_i 5.4 and 5.8 (external pH 3.8), but caused increased consumption of ATP by the cells, reducing the energy available for growth and cell division.[10] This was attributable to increased activity of a membrane-bound H^+-ATPase that coupled hydrolysis of ATP to expulsion of protons from the cell. When grown in the presence of benzoic acid, *S. cerevisiae* was also able to extrude benzoic acid by an energy-dependent process that probably involved a membrane-bound ATPase.[55] Evidence was reported that growth of *S. cerevisiae* in the presence of sorbate, 1 mM, at pH 4.5 induced two plasma membrane proteins, one of which catalyzed energy-dependent extrusion of sorbate and benzoate,[90] demonstrating the involvement of the type of mechanism suggested by Warth[113] and Henriques et al.[55]

At concentrations approaching the MIC, depletion of ATP may be a major factor leading to inhibition of microorganisms. Consequent inactivity of membrane-bound ATPases could lead to an accumulation of protons and preservative anions in the cytoplasm; both of these factors will then influence many intracellular enzyme reactions.

Several types of mechanism have been described that contribute to inducible acid tolerance and acid resistance in microorganisms.[4,97] Lowering of the internal pH can induce amino acid decarboxylases in some species; the amino acid decarboxylation can elevate the internal pH. The transition of bacteria from the exponential phase to the stationary phase is correlated with an increase in acid resistance and in general resistance to stress. Entry into the stationary phase is accompanied by a modification of sigma factors, proteins whose primary role is to bind to the core RNA polymerase, conferring promotor specificity.[76] The starvation sigma factor, σ^S (RpoS), encoded by the *rpoS* gene, has been identified as controlling stationary-phase adaptive processes in *E. coli*. A primary role of σ^S is as a factor controlling the production of stress-response proteins, induced during transition from the exponential phase to the stationary phase, but σ^S also has a role in the production of exponential-phase proteins.[4,43,76] Other regulatory proteins are also involved in response to acid stress.[43] Evidence has also been reported that during acid habituation of *E. coli* monounsaturated fatty acids present in phospholipids were either converted to their cyclopropane derivatives or replaced by saturated fatty acids, and it was suggested that increased levels of cyclopropane fatty acids may enhance the survival of microorganisms exposed to low pH.[13] During growth of *Clostridium acetobutylicum*, a decrease in pH of the medium from 6 to 5 was associated with a decrease in the ratio of unsaturated to saturated fatty acids and an increase in cyclopropane fatty acids.[68]

8.5 FACTORS INFLUENCING THE EFFECT OF pH, ACIDULANTS, AND ORGANIC ACID PRESERVATIVES

Combinations of inhibitory factors may be used in many foods, these combinations of factors may have effects that are additive, synergistic, or antagonistic; methods of distinguishing were discussed by Parish and Davidson.[87] An additive effect is one in which the combined effect of two (or more) antimicrobials is equal to the sum of the effect of each antimicrobial acting individually, whereas a synergistic effect is one in which the combined effect is greater than the sum of the effect of each antimicrobial. Clearly, the combined antimicrobial effect of pH and a preservative such as sorbic acid can be synergistic. For example, Figure 8-1 shows that adjustment of the pH of the medium to 5.1 with HCl had no effect on the probability of growth from single vegetative bacteria of proteolytic *Clostridium botulinum* at 30°C in 3 days, and 1,000 mg total sorbic acid l^{-1} in a medium at pH 7.0 had no effect on the probability of growth of single vegetative bacteria of proteolytic *C. botulinum* at 30°C in 3 days,[79] but the combined effect of addition of 1,000 mg total sorbic acid l^{-1} and adjustment of the pH to 5.1 reduced the probability of growth in 3 days by a factor greater than 10^5-fold (Table 8-9).

The antimicrobial effect of pH, acidulants, and weak organic acid preservatives in foods will be influenced by many of the components of the food including available sugars and amino acids and by the temperature at which the foods are maintained. The water activity (a_w) of a food could affect the pK_a of weak acids, and thus alter their antimicrobial effect, although in water-glycerol mixtures with an a_w between 0.80 and 1.0, the pK_a of sorbic acid at 25°C only varied between approximately 4.62 and 4.80.[89] The effect of acidulants and preservatives will depend on their chemical stability in the food and on whether they are degraded by microorganisms present. In many cases, the acidulants, such as acetic and lactic acids, are likely to have an additive or possibly a synergistic influence on the effect of weak organic acid preservatives, such as benzoic and sorbic acids. Many reports have been published describing the effect of these factors, singly and in combination, in foods.

In addition, the effect of organic acid preservatives is liable to be influenced greatly by the presence of a lipid phase. Uptake of lipid-soluble antimicrobials, in particular sorbic and benzoic acids and hydroxybenzoates, occurs into the lipid phase, reducing the effective concentration in contact with microorganisms contained in the aqueous phase. Only the undissociated acid is soluble in the lipid phase.

The distribution coefficient of sorbic acid, for example, can be defined as:

$$\frac{\text{concentration of sorbic acid in the lipid phase}}{\text{concentration of undissociated sorbic acid in the aqueous phase}}$$

The distribution coefficient defined in this way is independent of pH value and enables calculation of the amounts of undissociated and dissociated sorbic acid in the aqueous phase at any pH.[77] The distribution coefficients in peanut oil:water at 20°C were reported as: sorbic acid, 3.1 (95% confidence limits ±0.13); ethyl hydroxybenzoate, 26.0 (95% confidence limits ±1.5); propyl hydroxybenzoate, 87.5 (95% confidence limits ±2.1); and benzoic acid, about 6 at very low concentrations and about 13 at very high concentrations.[77] The solubility of these preservatives is similar in most types of oil, thus the distribution coefficients in other types of oil are probably similar to those reported above. For sorbic acid in mixtures of oil and water at about pH 5.0, roughly the same concentration of undissociated sorbic acid would remain in the water phase irrespective of the amount of oil present in the system (Figure 8-10). As the pH is decreased below 5.08, any increase in the ratio of oil to water in the system would result in a decrease in the concentration of undissociated sorbic acid in the aqueous phase. A greater proportion of parabens is taken up into the oil phase (Figure 8-11).

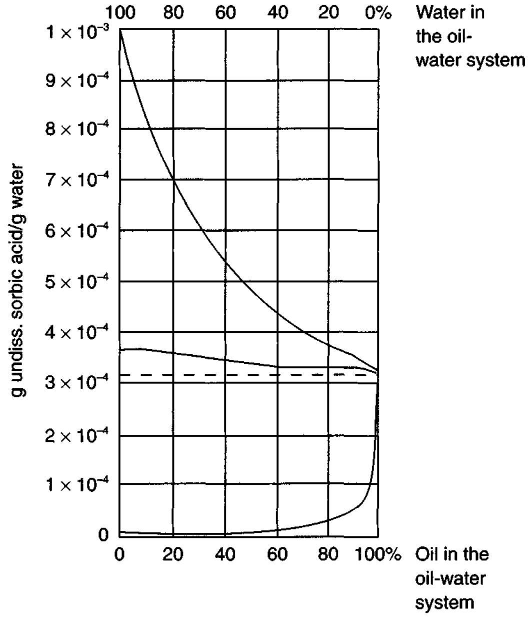

Figure 8-10 Concentration of Undissociated Sorbic Acid (g g^{-1} water) on Addition of 0.1 g Sorbic Acid to 100 g (water + peanut oil) at Various pH Values and with Various Amounts of Oil in the Oil-Water System. Lubieniecki-von Schelhorn, Investigations of the Distribution of Preservatives between Fat and Water in Foods, in *Microbial Inhibitors in Food,* N. Molin and A. Erichsen, eds., pp. 139–144, © 1964, Almqvist and Wiksell.

At the concentrations used in foods organic acids have little effect on the distribution of sorbic acid between oil and water phases, but the presence of high concentrations of glucose, sucrose, or sodium chloride reduces the solubility of sorbic acid in water.[49] It is clear that the antimicrobial effect of these preservatives is liable to be reduced markedly by the presence of fat in foods, eg, in emulsions, that the reduction in effect will be greatest in acidic foods, and that the reduction in activity will be greater in the case of hydroxybenzoates and benzoic acid than in the case of sorbic acid.

In foods that contain solid components, preservative factors may be less effective than in liquid foods because attachment of microorganisms to surfaces can increase their resistance to acid pH[93] and to other inhibitory factors. Immobilization of *Acetobacter aceti* in alginate beads or, to a lesser extent, adsorption on cellulose beads were reported to protect the bacterium from the effect of acetic acid,[65] although apparently the pH of these experiments was not reported.

8.6 CONCLUDING REMARKS

Microorganisms differ widely in their ability to multiply and to survive at low pH and in the presence of weak organic acids. An understanding of the effect of pH, acidulants, and organic acid preservatives on ability of microorganisms to survive and multiply is important as a basis for the most effective utilization of these factors in preservation of foods and in the elimination of microorganisms. Many reports have been published describing the effect of these factors, singly and in combination, on microorganisms in foods, and predictive models of the combined effect of temperature, pH, and acetic or lactic acid on growth of *Listeria monocytogenes* and of *E. coli* have been developed.[46,94] A great deal of information is available regarding the mechanisms of inhibition by pH and weak acids and of the mechanisms of microbial adaptation to multiply or to survive in the presence of these antimicrobial factors but further work is needed to provide an integrated understanding of these mechanisms.

  9.3 3 Chemistry of nitrite
  9.3.4 Antimicrobial activity of nitrite
9.4 Concluding remarks
References

9.1 INTRODUCTION

There is a widely recognized consumer-led desire to reduce the use of chemical additives, including antimicrobial preservatives, in foods.[31] However, many chemical preservatives continue to play an important role in ensuring satisfactory shelf life and safety of a wide range of foodstuffs. Antimicrobial preservatives used in foods, summarized in Table 2-6, Chapter 2, include acidulants (eg, inorganic acids such as hydrochloric and phosphoric; organic acids such as acetic, citric, lactic, malic, and tartaric), weak, lipophilic organic acid preservatives (eg, propionic, sorbic, benzoic acids, and esters), weak inorganic acids (sulfite, nitrite, carbon dioxide in modified atmosphere packaging), antibiotics (eg, the bacteriocin nisin, and the antimycotic natamycin [pimaricin]) and other products of lactic acid bacteria. Acidulants, organic acids, and esters are discussed in Chapters 8 and 31. The use of carbon dioxide in modified atmosphere packaging is covered in Chapter 10. Chapter 12 deals with nisin and other culture products, and Chapter 13 covers the other antimicrobials that occur naturally in foods. The most important of the other antimicrobial preservatives, the weak inorganic acids sulfite and nitrite, are covered in this chapter.

9.2 SULFITE

9.2.1 General

Sulfur, as an element, was well known in ancient times when the burning of sulfur was valuable as a means of purification and, as we say now, disinfection.[73] The burning of sulfur in containers, or in areas where foods and drinks were to be stored or prepared, generated sulfur dioxide gas (SO_2), providing a link with modern practice because sulfur dioxide is the predominant form in which sulfite is taken into microbial cells and inactivates them. However, today, the compound most often used to generate sulfur dioxide and the various anions with which it comes into equilibrium in foods is sodium metabisulfite ($Na_2S_2O_5$). Other compounds frequently used as sulfiting agents include sulfur dioxide itself, sodium and potassium salts of sulfite (Na_2SO_3; K_2SO_3), bisulfite ($NaHSO_3$; $KHSO_3$), and potassium metabisulfite ($K_2S_2O_5$). Calcium salts are also sometimes used. These salts all share the ability to generate free molecular SO_2, which correlates extremely well with their preservative activity. For this reason it is usual to calculate treatment levels for the various salts on the basis of their "SO_2 equivalents."

9.2.2 Uses in Foods

Sulfur dioxide is very reactive chemically[93] so it is not surprising that it is unusually multifunctional as a food additive. Its uses include: (1) the prevention of oxidative rancidity and other oxidation reactions, (2) the prevention of enzymic and nonenzymic browning reactions, (3) a bleaching agent and a color stabilizer, (4) the stabilization of ascorbic acid (vitamin C), (5) a flour improvement agent, and (6) an antibacterial and antimycotic (Table 9-1).[32,55,65,93]

The major uses of sulfur dioxide are in fruit and vegetable products and in alcoholic and nonalcoholic drinks, as well as a few applications in raw meat products and fish. In fruits and vegetables, sulfite is used mainly to prevent chemical and enzymic reactions that lead to deterioration, eg, in dried products or in products in which the water activity (a_w) has been otherwise reduced by the addition of solutes. Sulfite is used in drinks where the pH is low enough for an antimicrobial effect, mainly to prevent the growth of yeasts and molds. Applications in raw meat products aim to slow the growth of microorganisms and extend shelf life. An additional role of sulfite, not typical of other applications, is the improvement of safety through inhibition of the growth of Gram-negative food poisoning bacteria.[7,8] Since the functions of sulfite in foods vary widely, the applications and the concentrations required to perform a particular function vary widely as well. This is illustrated by the examples of sulfite usage worldwide (Table 9-2). The concentrations listed are illustrative because the maximum allowed levels differ in different countries.[61] In Europe, for instance, levels are authorized by European Union (EU) directives for sulfur dioxide (E220), sodium sulfite (E221), sodium bisulfite (E222), sodium metabisulfite (E223), potassium metabisulfite (E224), calcium sulfite (E226), calcium bisulfite (E227), and potassium acid sulfite (potassium bisulfite; E228).[61] In the United States (US), the use of sulfite in its various forms was generally regarded as safe (GRAS). However, reports that sulfite, particularly if inhaled as SO_2, could affect some individuals suffering from asthma has led to a more restricted and careful use.[54] The problem most often occurred following the use of high levels of sulfite as "salad fresheners" or by the addition of sulfite to acid foods, such as salads to which dressings are applied. Regarding the toxicity of ingested sulfite, in Europe the current acceptable daily intake for humans is 0.7 mg per kg body weight.[3] The average daily per capita consumption of sulfite from foodstuffs in Europe is about 20 mg SO_2, but may be five times more than this if alcoholic drinks are included.[2] The liver is capable of detoxifying gram quantities per day via the action of sulfite oxidase.[3] The efficacy of sulfite as an antimicrobial preservative (though not necessarily so in its other roles) is very pH dependent, for reasons that are well known (Section 9.2.3), with its effectiveness increasing greatly with reduction of pH. For this reason, products such as drinks, syrups, and purees are often acidified to ensure the required degree of preservation. This is particularly important in products such as syrups that contain high levels of sugars, because these products react chemically with sulfite and, because the reaction products are not antimicrobial, lead to a reduction in effectiveness during storage. The inhibitory activity of sulfite may fall during the storage of foods for other reasons also. For instance, in nonhermetically sealed containers it may oxidize to form sulfate, which is quite inactive in any of the functions for which sulfite is used. Many other reactions of sulfite with food ingredients lead to reductions in levels of free SO_2 (Section 9.2.3) so that, in contrast to most other food preservatives, it is important that such losses are taken into account, within legal constraints, in the design stages of product formulation, processing, and intended storage life.

Table 9-1 Preservative Functions of Sulfite in Foods

Function	*Example*
Antioxidant	Delays onset of oxidative rancidity and other oxidative deterioration reactions in foods during storage. Reduces color loss in meat, fruits, and vegetables. Aids retention of ascorbic acid (vitamin C) and carotenes during storage of foods.
Enzyme inhibitor	Prevents enzymic browning of fruits and vegetables caused by the activity of polyphenol oxidases.
Maillard reaction inhibitor	Prevents nonenzymic browning reactions between amino groups and reducing sugars by forming stable compounds with reaction intermediates.
Reducing agent	Improves rheology of flour by reacting with protein sulfydryl groups.
Antimicrobial	Inhibits growth of yeasts and molds in low pH and low a_w foods. Inhibits growth of Enterobacteriaceae and other Gram-negative bacteria in higher pH, high a_w foods.

Table 9-2 Major Applications of Sulfite in Foods and Levels of Use

Foods†	*Typical Use Concentrations (as SO_2: mg kg^{-1})*	*Major Purpose*‡
Fresh vegetables (onion, garlic, horseradish pulp)	50–1000	c, m
Frozen vegetables (white vegetables, mushrooms)	50	c
Dried vegetables	250–2500	c, o
Canned vegetables	20–200	c
Pickles	20–100	c, o
Peeled potatoes	10–50	c
Potato powders and flakes	100–500	c
Frozen potatoes	100	c
Fresh fruits	100	c, m
Dried fruits	100–2000	c, o
Fruit pulps, purees, and fillings	50–500	c, m
Fruit juices	10–100	c, m
Jams and jellies	50–100	c, m
Fruit-based sauces and related products	50–100	m
Sugar confectionary	50	c, m
Nonalcoholic beverages	20–200	m
Alcoholic beverages		
beers	10–30	m
wines	100–300	m
Vinegar	50–200	m
Sausage meat, burgers, and other meat products	450	c, m
Dried or salted fish	350–1000	c, o
Raw and frozen crustaceans	30–350	c, o

†Food uses and allowed concentrations vary greatly in different countries.
‡c: color retention; o: antioxidation; m: antimicrobial.

9.2.3 Chemistry of Sulfur Dioxide

The simple oxyanions of sulfur in its tetravalent states are salts of sulfurous acid (H_2SO_3), which one would expect to be formed when sulfur dioxide dissolves in water. However, comparison of Raman and infrared spectra of dissolved SO_2 with gaseous or liquid SO_2 have indicated that very little H_2SO_3 exists in solution. Dissolved SO_2 exists predominantly as the hydrate $SO_2{\cdot}H_2O$, or as a clathrate inside a shell of about seven water molecules.

The important equilibria that become established in foods are to form bisulfite:

$$SO_2{\cdot}H_2O \rightleftharpoons HSO_3^- + H^+$$

The bisulfite can then dissociate to form sulfite:

$$HSO_3^- \rightleftharpoons SO_3^{2-} + H^+$$

The first dissociation constant has a p*K* value of 1.86 at 25°C and zero ionic strength while the second, under the same conditions, leading to the formation of the sulfite anion, has a value of 7.18.[93] Consequently, in acid foods, there will generally be a mixture of hydrated sulfur dioxide and bisulfite anion present, while in near-neutral pH foods, bisulfite and sulfite will predominate. Figure 9-1 shows the expected relative concentrations of the various forms as a function of pH.

A further equilibrium that is of relevance in foods is the condensation of two bisulfite anions to form metabisulfite:

$$2HSO_3^- \rightleftharpoons S_2O_5^{2-} + H_2O$$

This equilibrium is only significant at high concentrations of bisulfite so that, at the low concentrations of metabisulfite that are employed in food preservation, the equilibrium will be well to the left and metabisulfite added as a preservative will rapidly dissociate to give bisulfite, and $SO_2{\cdot}H_2O$, depending on the pH.

The chemical reactivity of sulfite results from its strong reducing activity and its ability to take part in nucleophilic attack. Table 9-3 lists some of the important reactions in a food context that sulfite can undergo. The reactions that are most important in its antimicrobial activity include those with carbonyl groups, because these occur in aldehydes and ketones, which are present in many critical biological molecules, including proteins and some enzyme cofactors (eg, pyridoxal phosphate, folic acid). Pyridoxine reacts with sulfite to form an addition compound, so that nicotinamide adenine nucleotide (NAD$^+$) and (NADP$^+$) reactions can be interferred with. Thiamine is cleaved by sulfite to form pyrimidine sulfonate and a thiazole-containing product.

Proteins that depend on disulfide bonds for maintenance of their tertiary structures are sulfite sensitive, because sulfite can rupture these bonds to form thiosulfonate and thiol pairs:

$$-RSSR- + SO_3^{2-} \rightleftharpoons -RSSO_3^- = -RS^-$$

In this way sulfite may inhibit many of the critical enzymes within the microbial cell. Likewise, oxidized glutathione (GSSG) is susceptible to disrup-

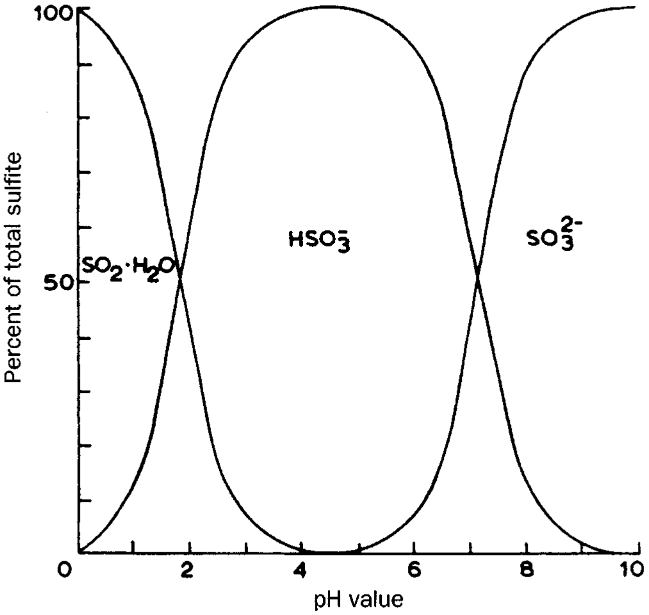

Figure 9-1 Relative Amounts of Sulfur Dioxide, Bisulfite, and Sulfite As a Function of pH. Plotted from the data of King et al.[43] *Source:* Copyright © 1989, A.H. Rose and B.J. Pilkington.

tion by sulfite. The pyrimidine bases cytosine and thymine in DNA and cytosine and uracil in RNA are subject to nucleophilic attack by sulfite. The purine adenine, present in adenine nucleotides (ATP; ADP; AMP), as well as in DNA and RNA, forms addition compounds with sulfite. Sulfite may accelerate the autoxidation of polyunsaturated fatty acyl residues in the lipids of yeasts and other fungi (but not bacteria).

There are therefore many means by which sulfite can interfere with the functioning of the most important molecules and reactions in microbial cells once it has gained access. The mechanism by which such access is gained is fundamental to the mode of action of sulfite as an antimicrobial preservative.

9.2.4 Antimicrobial Activity of Sulfite

The molecular mechanisms by which sulfite inhibits growth or inactivates microorganisms have received little attention, to some extent because it may react with so many critical components of a cell, as indicated above (Table 9-4). It is unlikely that there is just one specific reaction that is predominant in its effects on diverse organisms. The situation is made more complex by the effect of pH on the molecular form in which sulfite interacts with a microorganism. In different foods, the pH can range from below 3 to near neutrality. However, within the cytoplasm of bacteria, yeasts, and molds, homeostatic mechanisms operate to maintain a near-constant internal pH that is commonly near to 6.5.

Based on a close correlation observed between the intracellular accumulation of radioactivity from $^{35}SO_2$ in solutions at different pH values, and the estimated proportion existing as SO_2, it was proposed that it was molecular SO_2 that was taken up by cells of the yeast *Saccharomyces cerevisiae* var. *ellipsoideus*. While it was originally thought that active transport may have been involved, it was later demonstrated that SO_2 uptake by *S. cerevisiae* was predominantly passive, though a slow transport system for bisulfite ions that operated at low concentrations of the anion was tentatively suggested.[80]

S. cerevisiae accumulates SO_2 from solutions very quickly, reaching equilibrium within about 5 minutes and, at this time, the intracellular concentra-

tion can be many-fold greater than that in the surrounding solution. This occurs, and can be explained, when there is a difference in pH between the solution and the cell cytoplasm. With an intracellular pH of about 6.5 in *S. cerevisiae*, only about 0.0015% of free sulfite will exist as SO_2.[43] If the external pH is below 6.5, then SO_2 will diffuse into the cell and dissociate into HSO_3^- and H^+, thereby allowing further diffusion down its concentration gradient until the SO_2 concentration is the same on both sides of the cell membrane. Accumulation of sulfite by *Saccharomycodes ludwigii* and *Zygosaccharomyces bailii* was shown to occur similarly to that in *Saccharomyces cerevisiae*, resulting mainly from passive uptake of SO_2.[59,79] However, accumulation of sulfite in some other organisms appears to differ from this simple diffusion system. For example, studies of sulfate transport by *Candida utilis* indicated a common, active, energy-dependent transport system for sulfate, sulfite, and thiosulfite.[10,27] Sulfate analogues, including molybdate, selenate, and chromate, competitively inhibited the uptake of sulfate, as did sulfite and thiosulfate. Likewise, sulfite and thiosulfate inhibited sulfate uptake by *Penicillium chrysogenum*.[96] Selenate-resistant mutants of *C. utilis* had a defective transport system for sulfate, sulfite, and thiosulfate.[27] Although not being an important target for preservation by sulfite, *Desulfovibrio desulfuricans* was shown to possess a sulfite transport system[19] and mycelia of *Penicillium* and *Aspergillus* species were reported to transport sulfite.[89]

Therefore, with respect to transport of sulfite into microbial cells, it appears that free diffusion of molecular SO_2 is the major mechanism in those yeasts that are the most important targets for sulfite in food preservation, but alternative transport systems do occur in other organisms.

Interaction of sulfite with components of the plasma membrane have seldom been reported, though Stratford[78] did find that sulfite interfered with the accumulation of glucose and the amino acids arginine and lysine by *S. cerevisiae*. While this may have resulted from interaction of sulfite with a membrane protein, it is more likely that it resulted from collapse of the proton motive force.[73]

Having entered the cytoplasm, by whatever means, and been concentrated there (as explained above), the range of important molecules available for reaction with sulfite is high, so that many reactions that could lead to inhibition or cell death are possible, in addition to the acidification of the cytoplasm that will eventually occur if the external pH is sufficiently low. For example, it has been shown that just prior to cell death caused by sulfite, there is a rapid fall in ATP levels and a rise in free phosphate in *S. cerevisiae*.[74,75] Glyceraldehyde 3-phosphate dehydrogenase was shown to be the most sensitive enzyme on the Embden-Meyerhof-Parnas pathway, which is responsible for substrate level generation of ATP in *S. cerevisiae*.[38] Purified ATPase from yeast mitochondria was shown to be particularly sulfite sensitive.[47]

Different species of yeasts vary greatly in their resistance to sulfite. For instance, *Z. bailii*[85] and *Saccharomycodes ludwigii*[79] are much more resistant than *Saccharomyces cerevisiae*, which is generally regarded to be relatively sulfite tolerant, while *Kloekera apiculata* and *Hansenula anomola*[92] are much more sensitive. The sensitive strains are inhibited by about 0.2 to 1 mg l^{-1}, whereas some of the most resistant types tolerate up to about 20 mg l^{-1}. The reasons for these differences are not fully understood, but yeasts differ in their ability to bind sulfite[62] and binding by excreted acetaldehyde has been known for many years and has been proposed to play a role.[53,79]

While most of the antimicrobial applications of sulfite are directed at yeasts and molds in fruit and vegetable products and drinks at pH values well below neutrality, a small number of applications are directed at bacteria in raw meat products. These applications are primarily concerned with inhibiting the growth of spoilage bacteria, and consequently, extending shelf life. However, because these products, unlike many of the lowered a_w, low pH foods and drinks, have high water activities and pH values, an additional role of sulfite not found in most other applications is to improve safety by inhibiting the growth of any food poisoning bacteria that may be present. Sulfite is effective in this role because, although most active at low pH, it continues to influence the growth of microorganisms, including some types of bacteria, at pH values well above those typical of fruits and drinks and within the range typical of unfermented raw meat products.[11,20]

For example, the pioneering work of Dyett and Shelley[24] first showed that the predominant effect of adding sulfite to fresh sausages was to bring about a major change in the types of microorganisms that were able to grow. This, and later work, particularly of Banks and Board,[7] clearly demonstrated that sulfite caused a shift away from the Gram-negative–dominated flora of unpreserved meat and toward a Gram-positive flora largely consisting of *Brochothrix thermosphacta*, lactic acid bacteria, micrococci, and yeasts. The Gram-positive flora grew more slowly than the Gram-negative flora, so that the keepability of the fresh sausage increased when sulfite was added.

The general influence of sulfite and temperature together on spoilage flora are well illustrated by the data in Table 9-5. In Table 9-6, it is clear that even at a temperature as high as 22°C, a strong antimicrobial effect of sulfite is still noticeable.

The improvement of safety that derives from the use of sulfite in meat results first from the shift in flora from the Gram-negative types, that include contaminants such as *Salmonella* and *Escherichia coli*, and second from the effect of temperature. This was shown most convincingly by Banks and Board,[7] who conducted studies with *Salmonella*-inoculated sausages that were made with and without added sulfite and stored at different temperatures (Table 9-7). The first part of the table shows that Enterobacteriaceae were substantially inhibited in the sulfited products at 4°, 10°, and 15°C for at least 8 days, whereas growth occurred in the expected temperature-dependent manner in sulfite-free samples, even at 4°C. The second part of the table shows even more dramatic effects on the growth of *Salmonella virchow*, which did not multiply at 4° or 10°C, but at 15° and 20°C it was completely prevented from growing by sulfite, even though counts in the sulfite-free controls reached over 10^6 g^{-1} in 4 days at 15°C and in 2 days at 20°C. A similar pattern of responses was reported by Moerman et al.[51] using *S. typhimurium* and *E. coli.*

9.3 NITRITE

9.3.1 General

Preservation of meat and fish by reduction in water activity has been practiced since ancient times by drying or by the addition of solutes. Sodium chloride is the most-used solute for this purpose in the process known as curing. When naturally occurring deposits of salt containing nitrate as an impurity were used for curing, the nitrate became reduced to nitrite by microbial action, mainly due to micrococci and, in meat, reacted with the heme pigments to generate pink color. Later, naturally occurring deposits of nitrate (saltpeter; niter) were used deliberately. The origin of the use of nitrite itself is unclear, but followed the discovery prior to 1900 that it was the chemical species responsible for color development in cured meats. This resulted from its reaction with myoglobin and its derivatives to form nitrosomyoglobin.[56]

Today nitrite itself is therefore generally employed, usually mixed with sodium chloride in fixed proportion in "curing salts" so that variability in nitrite formation from nitrate is avoided. For instance, in Europe, while sodium nitrate (E251) and potassium nitrate (E252) can be used alone or mixed with sodium chloride, potassium nitrite (E249) and sodium nitrite (E250) can only be used mixed with sodium chloride.[61]

While curing has been widely accepted as a useful and safe procedure for many years, the demonstration in the late 1960s that potentially carcinogenic nitrosamines could be generated by reaction of nitrite with amino acids and amines in nitrite-containing foods, refocused attention on the role of nitrite, and on the possibility of finding alternatives for its various functions.[13] These concerns have led to reductions in the allowed nitrite input levels to foods from the levels of 200 mg kg^{-1} for many types of products toward the minimum required for satisfactory development of color, ie, probably about 20 mg kg^{-1} for most meat products.[95] For instance, in the US, maximum input levels are 156 mg kg^{-1}. Following the recommendation of a scientific panel, the US Department of Agriculture (USDA) restricted sodium nitrite to 120 mg kg^{-1} or potassium nitrite to

140 mg kg^{-1} in bacon (with 550 mg kg^{-1} ascorbate or erythorbate), and nitrate was no longer permitted. In Europe, levels depend on product type[13] (Chapter 18). Legislation varies greatly in other countries. For example, the use of nitrate and nitrite in foods has been almost abolished in Norway. In 1975 Canada banned the addition of nitrate to all but a few products, resulting in a five-fold decrease in residual nitrite in cured meats between 1971 and 1978.[5] In the United Kingdom (UK), a maximum residual concentration of 175 mg kg^{-1} is specified for nitrite in bacon, and for other cured meat products and canned meat products an indicative ingoing amount of 150 mg kg^{-1} and a maximum residual concentration of 100 mg kg^{-1} are specified, all as sodium nitrite.[77] In a survey in 1996–97 of products from retail outlets in England and Wales, in general the concentration of nitrite in bacon ranged from <0.2 to 120 mg kg^{-1} and that in other meat types ranged from <0.2 to 170 mg kg^{-1}.[46]

9.3.2 Uses in Foods

While nitrite is mainly used in meat curing, the addition of nitrate during the manufacture of certain cheeses has been practiced for nearly 200 years.[59] As in the earlier forms of meat curing, this leads to the generation of nitrite *in situ*, which prevents "late gassing" caused by *Clostridium tyrobutyricum* and *C. butyricum* in the stored product.[44] The procedure is widely used in Europe and, more recently in Canada,[5] though not in the US.

The range of cured meat products has expanded over the years to include unfermented raw meats, fermented raw meats, dry cured meats, cooked (pasteurized) meats, and canned products (see Chapter 18). They have in common the characteristic flavor resulting from the raised levels of salt and also, to some extent, from the nitrite,[34] the characteristic color, and the suppression of microorganisms that require a high a_w for growth. This results, in general due to the inhibitory effects of salt, in the selection of nonproteolytic microorganisms so that it is typical of these products that shelf life is extended and putrefaction is rare.[71,95]

The major reactions of nitrite, particularly with heme compounds,[9] have been comprehensively reviewed.[15,56] Effects on cured meat flavor were reviewed by Gray et al.[34] Several reviews address microbiological aspects relevant to cured meat products,[39,60,71,76,86,95] and to fish.[26]

9.3.3 Chemistry of Nitrite

Nitrite is the anion of a weak acid (nitrous acid), which has a p*K*a of 3.36.

$$HNO_2 \rightleftharpoons H^+ + NO_2^-$$

Most nitrite-containing foods have pH values within the range from about 5 to about 6.5, so that the concentration of free acid to be expected at equilibrium will be as low as 0.1% to 1% or so of the added nitrite.

While the detailed chemistry of color development during meat curing is complex, the main nitrosating reactions are well known, and the principal reactant is dinitrogen trioxide, which is the anhydride of nitrous acid:

$$2HNO_2 \rightleftharpoons N_2O_3 + H_2O$$

Reductants such as ascorbate or erythorbate, which are often added to cured products, accelerate color development by reacting with dinitrogen trioxide to produce nitric oxide:

$$N_2O_3 + HR \rightleftharpoons RNO + HNO_2$$
$$RNO \rightleftharpoons R + NO$$

where *R* is the reductant molecule.

Meat initally becomes brown when nitrite is added to it as heme compounds are oxidized. For example, purple-colored myoglobin (Mb) or red-colored oxymyoglobin (MbO_2), both containing iron in the ferrous state, are oxidized to brown-colored metmyoglobin, containing iron in the ferric state ($MbFe^{III}H_2O$). This may then react to form nitrosylmetmyoglobin ($MbFe^{III}NO$), which autoreduces to give the more stable Fe(II) form, nitric oxide myoglobin, or nitrosyl myoglobin (NOMb). This is the compound that gives the characteristic pink color to raw cured meats.[56] When cured meats are heated, the protein (globin) moiety in the myoglobin derivatives becomes denatured and detaches from the heme iron atom. The resultant color, typical of cooked cured meats, is then nitrosylmyochromogen (or nitrosyl protohaem). While these are the basic mechanisms of color formation, the details are complex, and new reactions are still being discovered.

Apart from the important color reactions, other reactions take place, some of which may be more significant microbiologically. Nitrite has an antimicrobial effect (Section 9.3.4) that increases as the pH is reduced so that, as with many weak acids, the unionized nitrous acid has been implicated as the active species since first proposed 70 years ago by Grindley.[33] However, antimicrobial effects additional to those attributable to HNO_2 have been often reported. In particular, heating of nitrite in bacteriological media produces a wide variety of products, including some that are much more antimicrobial than nitrite itself, first recognized by Perigo et al.,[58] and referred to as the "Perigo factor." Some of the compounds, particularly those derived from reactions between nitrite, cysteine, and ferrous ions, including nitrosyl-cystyl ferrate and more complex "Roussin black salts," were shown to be strong inhibitors of growth from spores of *Clostridium* species. Many other antimicrobial products, such as cysteine nitrosothiol,[40] have been described.[52] Some of these, while detectable and effective in culture media, were found to be much less easily detectable in foods[91] so that their importance in the microbiological stability of cured products remains doubtful. On the other hand, if some of these substances are deliberately added to foods (eg, S-nitrosocysteine to cured, pasteurized ham[90,91]), inhibition of growth from spores of *Clostridium* species could be demonstrated.

The problem of recognizing specific nitrite reaction products and assigning them particular antimicrobial roles has therefore been two-fold. First, the reaction products are numerous. Cassens et al.[14] used ^{15}N-nitrite in an attempt to identify the components of meat that reacted with nitrite. They failed to account for about 20% to 30% of the nitrite that was added. The remaining 70% to 80% had reacted with myoglobin (5% to 15%), sulphydryl-containing molecules (5% to 15%), lipids (1% to 5%), and proteins (20% to 30%). Some was lost as gas (1% to 5%), while 1% to 10% became oxidized to nitrate, and only 5% to 20% remained as nitrite. Second, antimicrobial activities of products reported to be generated in bacteriological media containing nitrite do not appear to be produced to the same extent in foods.[4]

9.3.4 Antimicrobial Activity of Nitrite

The antimicrobial activity of nitrite and its increased effectiveness with reduction in pH, first reported in the 1920s,[33] was confirmed and extended in more detailed studies by Tarr[82–84] and others, eg, for *Staphylococcus aureus*,[16] *Bacillus* spores,[25] and *Clostridium* spores.[58] At inhibitory concentrations, nitrite prevents outgrowth from spores rather than arresting their germination (eg, for *Bacillus* spores including *B. cereus*, *B. subtilis*, *B. polymyxa*, *B. coagulans*, and *B. licheniformis*) at concentrations of about 200 mg L^{-1} at pH 6[29] and for *Clostridium* species (eg, *C. sporogenes*[21,22]). It is interesting that nitrite can also actually cause spores to germinate, probably by cleaving bonds in peptidoglycan in the spore cortex, but only at higher concentrations and/or lower pH values than occur in foods, eg, thousands of mg L^{-1} at pH values less than 6,[23] so its practical relevance is doubtful. While effective minimum inhibitory concentrations for most organisms were about 100 to 200 mg kg^{-1} at pH 6 (eg, for species of *Achromobacter, Aerobacter, Escherichia, Flavobacterium, Micrococcus,* and *Pseudomonas*[84]), *Lactobacillus* and *Salmonella* were more tolerant,[16] as was *C. perfringens* when compared with other clostridia.[57]

The way in which nitrite interferes with the growth of microorganisms was reviewed by Woods et al.[95] They showed that it causes a rapid decrease in intracellular ATP levels. There is persuasive evidence that it brings about this decrease mainly by inhibition of the phosphoroclastic system in *C. sporogenes* and in *C. botulinum* A and B (proteolytic and nonproteolytic strains), C, D, and E.[94,95] This probably occurs somewhat analogously to the meat curing reactions, by reaction of nitrite with nonheme iron proteins such as the ferredoxins that play a key role in this system (eg, in *C. botulinum*[63]). Action of nitrite on the phosphoroclastic system was enhanced by ascorbate, and nitrite plus ascorbate was shown additionally to inhibit a wide range of 2-oxo acid oxidoreductases.[95]

Bearing in mind that (1) input levels of nitrite in most countries do not exceed about 200 mg kg^{-1}, (2) losses occur by reaction with food components, and (3) in many cured meat products the pH is above 6, the importance of nitrite as an antimicrobial in foods has often been questioned. In cheeses, in which the pH is low, the efficacy of nitrite as a spore-control agent is, of course, not doubted. In fermented meats, likewise, antimicrobial activity should be expected. This may be important in the inhibition of environmental contaminants such as *Listeria monocytogenes.*[12,41,42,50] This is well illustrated by the data in Table 9-8, in which the effects of combinations of salt, nitrite, and pH on growth of *L. monocytogenes* are compared. Even at concentrations up to 100 mg kg^{-1}, little inhibition is evident at pH 6. However, at pH 5.3, substantial inhibition is shown at 50 mg kg^{-1}. This combination of salt, pH, and residual nitrite is relevant to a number of salami and similar fermented meat products.[42,43] Likewise, studies with *S. aureus* found no inhibition of growth and enterotoxin A production by 200 mg kg^{-1} at pH 6.6.[48] *S. aureus* is capable of growth and enterotoxin formation aerobically in nitrite-containing sausages and bacon,[18,28] but inhibition becomes apparent as the pH is reduced.[87] Whereas the antimicrobial effects of nitrite are therefore well established, and may be important in the preservation and safety of the lower pH foods, their relevance in higher pH foods has been less clear. In particular, attention has centered on the possible role of nitrite in the prevention of outgrowth from spores of *C. botulinum* in vacuum packed cured products, raw meat products (such as bacon), and heated products (such as cooked hams and nitrite-containing sausages).

A series of studies by Roberts et al.[66–69] investigated the combined effects of pH, salt, nitrite, and ascorbate in pork slurry on the probability of growth from spores of *C. botulinum*. The study led to a mathematical model for predicting the effect of these parameters on *C. botulinum* growth.[72] The most important factors influencing growth from spores were pH value and salt concentration. Other food systems studied have included vacuum packed cured meats and liver sausage, pasteurized cured comminuted pork, and shelf-stable canned cured meats. Hauschild et al.[36] summarized data from these numerous product-specific *C. botulinum* challenge tests and tried to estimate the degree of safety contributed by nitrite on a "probability of growth from one spore" basis. The influence of nitrite could be seen clearly in many of the experiments considered. A particularly striking example was given by Tompkin et al.,[88] who inoculated cured pork with spores of *C. botulinum* A and B while arranging that the same *input* levels of nitrite would deliver different *residual* levels. This was done by adding extra hemoglobin to react with, and therefore reduce, residual nitrite levels when required. The results (Table 9-9) showed that the highest residual levels delivered the most effective inhibition, whereas the lower residuals were less inhibitory, in order of decreasing concentration and whatever the input level. Pasteurization in these experiments was at 74°C. With more severe heating, there is ample evidence that spores that survive the heat process are injured. Injury is expressed as increased sensitivity to a variety of antimicrobial agents and to environmental parameters that are not optimal for growth.[1,30] Nitrite is among the antimicrobial agents that become more inhibitory following heat damage to spores. For example, heat treatment of spores of *C. sporogenes* PA 3679 at 115°C for 5 minutes caused about a 10^2-fold decrease in colony count as estimated by plating on a nutrient agar at pH 6.8, while addition of 50 mg L^{-1} of sodium nitrite to the medium resulted in a 10^5-fold decrease.[70] After heating at 90°C for 6 hours, growth from spores of *C. perfringens* was much more sensitive to inhibition by nitrite as well as by salt than was growth from spores that had simply been heat activated.[17] Lucke[45] reported that *D*-values of *C. botulinum* types A and proteolytic B at 100° and 105°C were much longer in liver sausage mixture (prepared from precooked ingredients) than in Bruhwurst (made from raw ingredients only). Nitrite did not prevent development of the surviving spores in the liver sausage, but was markedly inhibitory in the Bruhwurst. It was concluded that fat in the liver sausage protected spores from heat injury and, as in the studies of Tompkin et al.,[87] that nitrite was inactivated by iron derived from the liver.

Many such cured meat products, especially liver sausage and blood sausage, would become unacceptable to consumers if they received a full botulinum cook of F_0 2.5. Shelf-stable cured meat products such as canned luncheon meats, hams, and sausages in hermetically sealed containers are therefore usually heated only to F_0 0.2 to 1.0 or so. They rely for their stability and safety on combinations of the low incidence of spores in the raw materials (numbers of *C. botulinum* spores in 138 samples of Canadian liver sausage[35] were estimated to be about 0.15 kg^{-1}), heat damage to any spores that are present, and their sensitivity to inhibition by salt and nitrite.[45,86]

While such experiments show that nitrite does have an antibotulinal effect, and under the conditions relevant to cured meats, its quantification and extrapolation to practical issues of food safety have been less easy to make. For example, while the experiments summarized in Table 9-9 show that without doubt, by moving from 112 to 84 to 30 to 6 mg kg^{-1} of nitrite in the particular pasteurized ham, the probability of spore outgrowth is increased, even the highest levels of nitrite did not completely prevent outgrowth of all the 10,000 or so spores that were originally present in each can and so did not deliver the equivalent of a classical 12-D process.

Hauschild et al.[36] summarized the implications of such observations by concluding that (1) the degree of safety of the cured products that had been studied differed by several orders of magnitude and (2) large reductions in the concentrations of nitrite in the products could have severe consequences. Hauschild and Simonsen[37] further concluded, "Research data are limited and do not allow us at present to propose minimal requirements of the essential safety factors. Instead, our risk assessment relies heavily on commercial practice and experience."

At the request of the USDA, the US National Academy of Sciences considered the health and

Table 9-9 Influence of Residual Nitrite Levels on Inhibition of Growth from Spores of *Clostridium botulinum* in Pasteurized Cured Pork

Initial $NaNO_2$ (mg kg^{-1})	*Hemoglobin Added (%)*	*Residual Nitrite (mg kg^{-1})*	*Swollen Cans (25 per variable) after (days)*[†]				
			20	*40*	*60*	*80*	*100*
156	0	112	1	2	2	2	13
156	1	84	1	1	3	16	25
50	0	30	3	4	19	25	25
50	1	6	25	25	25	25	25

[†]The inoculum consisted of 10^2 spores of *C. botulinum* A (5 strains) and proteolytic B (5 strains) per g in pasteurized cured pork in cans. Salt concentration was 3.53% to 3.98%. Pasteurization was in 77°C waterbaths to a center temperature of 74°C. Incubation was at 27°C.

safety aspects of dietary nitrate and nitrite and possible nitrite alternatives.[5,6] It was concluded that "it is not possible to estimate the potential morbidity or mortality from *C. botulinum* if nitrite were to be removed as a curing agent from certain products" and "in view of the possible but unquantified risk resulting from the use of nitrite as a curing agent, the search for alternatives to the use of nitrite should continue." It is because of all these considerations that there remains a well-founded reluctance to accept further relaxation of the basic preservation systems, including the contribution made by nitrite, that operate in cured meats.

Nitrite alternatives that have been proposed have included the addition of other antimicrobials such as sorbate, alone or with reduced levels of nitrite.[49,64] Other approaches, particularly in Canada, have aimed to deliver the necessary color to cured products by the addition of preformed heme-nitrite reaction products[54] although, while reducing nitrite levels, this sort of approach leaves open the microbiological consequences.

Following a USDA initiative to reduce input levels of nitrite in bacon to a maximum of 120 mg kg^{-1}, and to require the addition of 550 mg kg^{-1} of ascorbate or isoascorbate, a novel approach was developed. In this approach (the "Wisconsin process"), a combination of 40 to 80 mg kg^{-1} of sodium nitrite and a readily fermentable carbohydrate (minimum 0.7% sucrose) plus an acid-producing culture (eg, *Pediococcus acidilactici*) is added,[81] so that pH is reduced, enhancing the effectiveness of the nitrite that is present and, should the product be stored too long or at too high a temperature, further acidification is ensured.

9.4 CONCLUDING REMARKS

Sulfite and nitrite both deliver benefits to foods that do not rely on their antimicrobial activities, such as the enhancement of flavor, color, and antioxidant activity. However, they are the only inorganic preservatives that have clear antimicrobial activities as well. Both are most effective at low pH values, and this is widely exploited in the case of sulfite in a variety of acidified products, but is less relevant for nitrite, where most of the applications are in foods that are not substantially acidified. Partly for this reason, sulfite plays a much more obvious role than nitrite as an antimicrobial preservative.

Both anions have been associated with undesirable potential toxicological effects, so that there has been interest in reducing their levels or eliminating them from foods and in finding alternatives for them. However, to some extent because of the multifunctionality, widely effective alternatives have been difficult to find. At the same time, reductions in levels have been approached with caution because of the possibility of increased risk of food poisoning. This is so for the use of sulfite in meat products in some countries, but more so with respect to the antibotulinal role of nitrite in cured meat products that, although there are still conflicting data, most authorities agree it would be unwise to lose.

10.1 INTRODUCTION

10.1.1 General

The shelf life of food can be enhanced by modifying the gas composition of air, ie, increasing or decreasing the oxygen content and/or increasing the level of carbon dioxide. Nitrogen levels may be varied to displace oxygen or to act as an inert filler that keeps flexible packages from collapsing but has no biological activity.

It is understandable that limiting access to oxygen will affect aerobic organisms, however, as early as 1877, microbiologists had demonstrated the inhibitory effects of carbon dioxide on microorganisms.[127] During the period from 1880 to late 1920, about one hundred reports were published within this field.[153] The following was concluded: (1) high pressures of carbon dioxide can inactivate some types of microorganisms; (2) high concentrations of carbon dioxide, at normal atmospheric pressure, can be inhibitory for many types of microorganisms, though the sensitivity to carbon dioxide varies between wide limits; and (3) increased concentrations of carbon dioxide are required for growth of certain organisms.

The findings that the growth-inhibitory effects were different for different organisms, confirmed by Coyne[22] and Haines,[73] is important for an understanding of food spoilage flora under modified atmospheres. Hence, modified atmospheres not only reduce microbial growth rates, but also they may impose changes in the composition of the microbial flora and may even improve the growth of some microaerophiles. This chapter will deal mainly with the controlling effect of modified atmospheres on the composition of the microflora, ie, on the types of microorganisms that make up the dominant spoilage microflora under different storage conditions.

10.1.2 Terminology and Technique

Storage of food under modified atmospheres (MA), ie, an atmosphere where the ratios between the air components have been changed (modified atmosphere packaging [MAP]), can be achieved in several ways. Usually the term modified atmosphere implies the use of some form of package based on a laminated plastic film with a substantial head space, at least at the moment of packaging. However, a "vacuum package" also provides a modified atmosphere; air is removed and the head space is decreased. In this limited space the product and/or the metabolic activities of contaminating microorganisms change the proportions of oxygen and carbon dioxide. To distinguish between a vacuum package where the atmospheric modification is passively created, and the type of package where gas has been deliberately flushed into the package, the term "gas package" has been used. However, the term is mostly avoided in the industry because of the possible negative implications.

The permeability of the packaging film to different gases is of major importance for the efficiency of the procedure. Many films of different qualities are on the market but they are beyond the scope of this discussion.[117,123,125] The most gas-impermeable materials available are those that include a layer of aluminum in the laminate.

The atmosphere in vacuum packages or modified atmosphere packages can be controlled by the use of oxygen absorbers or carbon dioxide emitters (active packaging). These techniques can also be used to introduce or withdraw other components in the package, eg, ethylene, which affects the ripening of fruits and vegetables, or ethanol, which suppresses mold growth and retards the staling of bread. The industrial use of oxygen scavengers and ethylene absorbers is increasing, especially in Japan and the United States (US).

Another technique for changing the atmosphere around food is to change and maintain the atmosphere directly in a storage room or in a larger container. This is done by continuously controlling the gas composition, the so-called controlled atmosphere (CA) storage. This procedure was commercially applied for fruits as early as 1928.[143]

Another early application of the concept of changing the gas environment was the carbonation of drinking water.[51,80] It was found that carbonation increased both the shelf life and the safety of the product.[153] In the 1950s, interest in using high carbon dioxide pressures for the inactivation of microorganisms was pursued.[77,78] This concept has been taken up again, and is now supported with new techniques that make it feasible to treat food at very high pressures (5–35 MPa).[2,155] Five atm (505 kPa) of carbon dioxide extended the time to reach 10^6 colony-forming units per cm^2 of pork by about three times compared with storage under 1 atm (101 kPa) of carbon dioxide, at 4°C.[8] The increased pressure had no significant effects on the composition of the spoilage flora.[8] However, this chapter will be limited to modified atmospheres at atmospheric pressure provided by current packaging techniques and employing flexible packages.

10.2 THE EFFECT OF OXYGEN ON MICROORGANISMS

Oxygen is toxic to all life provided the partial pressure is high enough. Explanations of its toxicity include the following: (1) inactivation of certain enzymes, (2) increasing intracellular generation of hydrogen peroxide, (3) oxidation of membrane lipids, and (4) *in vivo* production of the superoxide radical. These effects may coincide but formation of superoxide radicals is probably of major importance.[74] For example, oxygen resistance of cells can be correlated with their superoxide dismutase activity.[70,104] Dismutation of superoxide radicals gives rise to hydrogen peroxide that, if not rapidly destroyed by catalase, in turn, can react with further superoxide radicals, resulting in the formation of extremely reactive compounds, such as the hydroxyl radical.

Different types of organisms are protected to various degrees against the oxygen radicals. Superoxide dismutase is important for protection but simultaneous action of other defense enzymes, including catalases and peroxidases, is required for removal of the hydrogen peroxide formed in the dismutation reaction.[76] Most aerobic and facultatively aerobic microorganisms can endure the partial pressure of oxygen in air, but microaerophilic organisms can be inhibited by this concentration of oxygen. The partial pressure of oxygen in air is usually toxic for anaerobic organisms that lack efficient systems to get rid of the oxygen-generated radicals.

Organisms able to utilize oxygen have an ecological advantage. Oxygen metabolism results in a high energy yield. Thus, the toxic effects of oxygen are, in practice (ie, up to 100% of the gas phase under atmospheric pressures), of minor importance in connection with microbiological food spoilage. More important is the growth-supporting effect of oxygen because organisms with aerobic metabolism, in the presence of oxygen, always will outgrow those lacking this ability under otherwise unrestricted conditions.

Pseudomonas, *Psychrobacter*, and *Shewanella* are aerobic genera, but they can also grow under anaerobic conditions provided that there is a suitable electron acceptor present. *Shewanella putrefaciens*, for example, is able to reduce trimethyl-amine-oxide in fish to trimethyl-amine.[93,96] Many bacterial taxa can grow in both aerobic and anaerobic environments, eg, *Enterobacteriaceae*, *Aeromonas*, *Photobacterium*, *Brochothrix*, and lactobacilli. Lactobacilli, including the genera *Lactobacillus*, *Pediococcus*, *Leuconostoc*, and *Weissella*, differ within wide limits in their response to oxygen. The taxa that are microaerophilic compete best with other types of bacteria in the presence of traces of oxygen. Strictly anaerobic organisms (for example, *Clostridium* and *Bifidobacterium*) seldom dominate during food spoilage. Multiplication of clostridia to high numbers in food usually requires either that the normal spoilage flora has been killed (together with storage at anaerobic conditions), or that a heavy population of other organisms provide the anaerobes with an oxygen-free growth environment.

10.3 THE EFFECT OF CARBON DIOXIDE ON MICROORGANISMS

10.3.1 Mechanism of Effects

Carbon dioxide has an important regulatory influence in the living cell. All cells require carbon dioxide for growth, but if the partial pressure of carbon dioxide increases over a certain critical level, metabolic activity will be retarded.[15,22,127,153]

Several hypotheses to explain the growth-inhibitory effects of carbon dioxide have been put forward. Some examples are that carbon dioxide should: (1) cause a decrease of the intracellular pH,[22,158] (2) inhibit (or stimulate) enzymatically catalyzed reactions and enzyme synthesis,[32,87] and (3) interact with the cell membrane.[39,42,133] There are probably two major effects involved: (1) effects of both aqueous carbon dioxide and HCO_3^- on the state of the cell membranes and/or the function of the membrane proteins, and (2) effects on cytoplasmic enzymes. The former effects are probably the most important ones in those organisms that are relatively resistant to carbon dioxide (see below), ie, where a relatively high level of carbon dioxide is required for growth inhibition. However, for more sensitive organisms that are affected by small increases in the partial pressure of carbon dioxide, interference with enzymes and their activities is probably more important.[87] It has also been concluded that "most probably, a major factor in the efficacy of carbon dioxide lies in its ability to penetrate the bacterial membrane, causing intracellular pH changes."[32] Generally speaking, carbon dioxide inhibition of microbial growth cannot be attributed to a single target in the cell. Inhibition by carbon dioxide seems to be the overall result of a complex interaction with several key physiological reactions. The likely mechanisms involved in carbon dioxide inhibition have been thoroughly reviewed.[32,87]

10.3.2 The Effect of Concentration

The solubility of carbon dioxide in water is high. Carbon dioxide distributes approximately equally per unit volume between the gas phase and the water phase.[35] At moderate temperatures and below 1 atm (101 kPa), if the concentration of carbon dioxide in the gas phase is in equilibrium with the solution, the solubility follows Henry's law ($[CO_2]aq = k_H pCO_2$, where pCO_2 is the partial pressure in atm of carbon dioxide in the gas phase and k_H is the Henry's law constant in units of mol atm^{-1}). The proportionality of solubilities and partial pressures may be assumed under atmospheric pressure.[132] The concentration of carbon dioxide is often given as the percent of carbon dioxide in the gas phase at atmospheric pressure.

The carbon dioxide molecule can, in water, be hydrated to carbonic acid, and then further dissociated to bicarbonate and carbonate as follows:

$$CO_2 + H_2O + \mathbf{CO_2[H_2O]} \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+ \leftrightarrow CO_3^{2-} + 2H^+$$

The ratio of these forms in the aqueous phase is dependent on several factors, including the pH. The hydration of carbon dioxide to H_2CO_3 takes time because of the rearranging of the valence bonds between the carbon and the oxygen, but the dissociation is quick.[35,72] The equilibrium of hydration ($\mathbf{CO_2[H_2O]} \leftrightarrow H_2CO_3$) is much displaced toward the unhydrated side, meaning that the hydrated form normally can be neglected, and the system of the carbonic acid is represented by **solvated** carbon dioxide ($CO_2[H_2O]$). The distribution of carbonate species as a function of pH is shown in Figure 10-1.

The retarding effect of carbon dioxide on bacterial growth increases along with increasing concentration[41,67] (Figure 10-2). In the figure the growth rate decreases throughout the range of carbon dioxide concentrations tested, but the decrease is steeper at the lower range of concentrations. This trend is also in agreement with other observations.[20,67,68]

Carbon dioxide resistance is different for different types of microorganisms. Examples of carbon dioxide–sensitive organisms are frequently found in the genus *Pseudomonas* and among many of the molds that are associated with food. Their growth is often significantly retarded at a partial pressure as low as 10 kPa (0.1 atm or 10% [v/v] carbon dioxide in the gas phase at atmospheric pressure).[54,99,109,156]

Bakers yeast (*Saccharomyces cerevisiae*), on the other hand, is unaffected by up to about 51 kPa (0.5 atm),[18] while the genus *Lactobacillus* is affected only slightly at 100 kPa of carbon dioxide (1 atm).[110] As much as 869 kPa (8.6 atm) of carbon dioxide was required to reduce the maximum specific growth rate of a strain of *Lactococcus lactis* subspecies *cremoris* by 50%.[41]

The growth resistances to carbon dioxide of some strains of different species are compared in Figure 10-3. The strains were tested under anaerobic conditions. Aerobically growing organisms seem often to be more sensitive to carbon dioxide than anaerobically growing ones.[41,68] However, anaerobic species do not necessarily possess higher resistance to carbon dioxide than facultatively anaerobic ones (Figure 10-3), and the resistance can differ between different strains of the same species.[86] Figure 10-3 demonstrates that there is no general difference in resistance between Gram-positive and Gram-negative genera as sometimes has been stated in the literature.[141,147] On the other hand, lactobacilli are relatively resistant to carbon dioxide, which is in accordance with observations from packaging experiments using modified atmospheres[23,82] (see below).

The relative inhibition was calculated as the ratio between the maximum specific growth rate in 101 kPa carbon dioxide and the maximum specific growth rate in 6 kPa (0.05 atm) carbon dioxide in nitrogen. *Source:* Copyright © 1989, Göran Molin.

10.3.3 The Influence of Temperature

The growth-inhibitory effect of carbon dioxide is strongly affected by temperature. The inhibitory effect of a certain partial pressure of carbon dioxide in the gas phase increases with decreasing temperature.[43,67] In the case of *Pseudomonas fragi* (strain ATCC 7943), this is due to the increase in water solubility of carbon dioxide at decreasing temperatures.[43] Thus, the solubility of carbon dioxide in water increases with decreasing temperature, and the vegetative microorganisms, mainly consisting of water, and enclosed by the water phase, are exposed to a higher carbon dioxide concentration when the temperature is low. This is also true if the bacteria are growing on a food surface, eg, a meat surface. Furthermore, there can be an additional inhibitory effect as a result of the lowered temperature itself. This was indicated for a mesophilic strain of *Bacillus cereus*, which had a carbon dioxide resistance about twice that of *P. fragi* ATCC 7943.[43] The additional effect must, of course, be dependent on how effectively the organism combats the effects of low growth temperatures. *P. fragi* grows relatively well down to the freezing point of the substrate. Thus, the shelf life of food under a carbon dioxide-enriched atmosphere is prolonged by low storage temperatures (see Figure 10-5, and below).

10.3.4 The Influence of pH

In water, the aqueous CO_2 molecules are in equilibrium with H_2CO_3, HCO_3^-, and CO_3^{2-}. The concentration of carbonate ions (CO_3^{2-}) at pH below 8.0 is too low to be of any biological significance and at pH below 6.0, the major portion of dissolved CO_2 exists as hydrated CO_2 molecules (H_2CO_3 constitutes only a small fraction of aqueous CO_2). Thus, there are two molecules to take into account, CO_2 and HCO_3^-. The former dominates at pH values below the pK_a (6.37) for aqueous CO_2/HCO_3^- and the latter above. Both CO_2 and HCO_3^- have biological effects but their relative inhibitory effects are not known.[32,87] However, there is evidence that CO_2 may have the greater effect on spore germination.[39]

The growth-retarding effect of carbon dioxide on *Pseudomonas fragi* (ATCC 7943), growing in fermenter cultures under continuous sparging with the tested gas mixtures, was not affected by pH in the range of 5.7 to 6.7.[43] On the other hand, the extension of shelf life due to vacuum packaging is lower for dark-cutting, high-pH beef (pH 6.2–6.7) than for normal beef (pH below 6.0).[46,128,150] This indicates that pH may affect inhibition by carbon dioxide in closed systems (packages) where the available amount of carbon dioxide is limited. A substantial amount of carbon dioxide is accumulated in a vacuum package of meat, and this carbon dioxide is the major reason for the shelf life prolonging effect (see below).

10.3.5 The Influence of Growth Medium

The growth-inhibitory effect of carbon dioxide in the gas phase is dependent on its solubility in the medium surrounding the microorganisms. The amount of carbon dioxide that can be dissolved in a medium decreases with decreasing water activity, and increases with increasing buffer capacity.[102] However, even though a lowered water activity reduces the amount of dissolved carbon dioxide in the medium, its antimicrobial action will enhance the growth-inhibitory effect of carbon dioxide.[6]

The inhibitory effect of carbon dioxide on the growth of organisms is influenced by the nutritional situation, for example, by the carbon source that is being utilized.[67,89] The catabolism of amino acids by *Pseudomonas* species was especially sensitive to increased levels of carbon dioxide while that of glucose was less affected.[111,148]

10.3.6 Additional Factors

A crucial factor in the use of modified atmosphere to prolong shelf life is that the product has a low contamination level at the time of packaging.[1,105]

A factor that will influence the change in gas composition in the package during storage, and hence the partial pressure of carbon dioxide in the package, is the head space–to–product volume.[159] The relevance of this factor must be considered for each individual type of application.

10.4 THE USE OF MODIFIED ATMOSPHERES IN PRESERVATION OF FRESH MEAT

10.4.1 Spoilage

The initial microflora of meat, for example, beef, lamb, pork, and poultry, always represents a complex mixture originating from skin and mucous membranes, and from environmental sources such as soil and water. Typical groups present are *Acinetobacter*, *Pseudomonas*, *Flavobacterium*, *Psychrobacter*, *Moraxella*, coryneforms, *Enterobacteriaceae*, *Staphylococcus*, and *Micrococcus*.[8,9,23,26,45,46] But even if the microbial variety is huge, the total numbers of organisms are usually relatively low. The environment then enforces a selection pressure on the microflora, and the types of organisms most fitted for the specific environment will outgrow the others, become dominant, and reach high numbers and spoil the meat. The microbial spoilage point of a food can be defined as "the time at which the activities of microbes present in a product become offensively evident to the senses."[62]

Irrespective of whether the meat originates from beef, lamb, pork, or poultry, the typical spoilage flora of refrigerated meat stored at 8°C or lower in air is composed mainly of *Pseudomonas*,[4,9,23,46,65,107,108] with *Pseudomonas fragi* as the most frequently dominating species, followed by *Pseudomonas lundensis* and certain biotypes of *Pseudomonas fluorescens* (especially biovariant 1).[23,115,116] Occasionally *Psychrobacter* (*Psychrobacter immobilis*) may reach significant numbers.[23]

The interior of fresh meat from healthy animals is almost free of bacteria and other microorganisms. The surface is where that the microorganisms multiply and reach numbers high enough to cause spoilage. As a general rule, meat acquires an offensive odor when the bacterial flora reaches about 10^7 colony forming unit (CFU) cm^{-2} of meat surface, and when the numbers have reached about 10^8 CFU cm^{-2} the meat surface becomes slimy.[23,64,83,112] At this point, the easily available nutrients on the surface become depleted, the microbial flora starts to become proteolytic and penetrates into the meat.[24,83] Before the bacteria attack the protein, they utilize more easily available carbon and energy sources; proteins must be hydrolyzed to amino acids before they can easily be utilized. Easily utilized compounds in meat, other than free amino acids (about 0.4% [w/w]) are, for example, lactic acid (0.9%) and glucose (0.01%).[60,111] In spite of these relatively low concentrations, the spoilage flora can be well supported up to around 10^7 CFU cm^{-2} due to diffusion of nutrients from the interior of the meat.[23]

Pseudomonas species that cause spoilage of meat have a comparatively high growth rate at refrigeration temperatures. On the meat surface, they primarily grow by using free amino acids, lactic acid, and glucose and, when they reach higher cell concentrations, they eventually produce lipases and proteases. Off-odors result primarily from the production of ethyl and methyl esters, short chain fatty acids, and sulfur-containing compounds.[23,36] From the bacteriological point of view, no general differences exist among the spoilage of meat from cows, pigs, lambs, and poultry. However, the shelf life can differ because of differences in contamination levels, the pH of the meat (the pH is relatively high for poultry: 5.7–6.7),[107] and the ratio between meat surface and volume, which is often high for poultry.

10.4.2 Vacuum Package

The vacuum package is the most frequently used package type for meat where a modified atmosphere is applied. The meat is put into a pouch made of a suitable plastic film, the air is evacuated, the pouch collapses around the product, and the pouch is sealed. Other technical procedures are also used, eg, a hot web can be molded to the meat on a stiff lower web by establishing a vacuum on both sides of the upper web, then the vacuum above the upper web is released (vacuum skin package).

However it is produced, a vacuum packed product is encircled by a plastic film that ideally should be gas impermeable. There is no vacuum inside these packages. The air space is strongly restricted, and the proportions of oxygen and carbon dioxide are altered by the scavenging of oxygen by the meat and the microflora, and by the production of carbon dioxide. These changes affect the metabolism of the microflora (growth and end-product formation), and the product's shelf life will be prolonged.

The evolving carbon dioxide in a meat package can originate from the following: (1) diffusion from a preformed pool in the meat, (2) aerobic energy metabolism of meat cells, (3) other biochemical reactions of the meat cells, and (4) microbial activity.[44] It is not clear which of these are the most important. However, the presence of oxygen seems to be of minor importance for the initial carbon dioxide production, when about 2×10^{-3} ml carbon dioxide cm^{-2} of meat surface per hour is produced.[44]

Provided the vacuum package is gas tight, the partial pressure of carbon dioxide ideally will gradually approach 1 atm (101 kPa) and the partial pressure of oxygen will decrease below normal detection levels (<0.0001 atm = <10 kPa). In heat-treated meat, however, the rate of production of carbon dioxide and oxygen scavenging decrease. The change of the gas phase is, in this case, mostly due to microbiological action alone.

Because carbon dioxide is highly soluble in water, even after a considerable amount has been produced, the appearance of the package can remain largely unaffected. In vacuum packaged fresh meat that has been chill stored for some days, the concentration of carbon dioxide will be expected to be least 20% to 40% (v/v),[138] and frequently it is around 90% (v/v), measured in the tiny head space of the package,[112] and the oxygen concentration will be below 1% (v/v).[112,138] The concentrations vary and are dependent on several factors, eg, the quality of the package film, head space, storage temperature, meat quality, and the composition and activity of the microflora.[62] From the bacteriological point of view, this is the major drawback with the vacuum packaging of meat, ie, even if a satisfactory shelf life is achieved in a majority of the packages, there will always be a certain number with an unsuspected short shelf life, due to leakage and/or unsatisfactory carbon dioxide generation. As a consequence, the safety margin between maximum obtainable shelf life and the storage time must be kept wide.

In general, vacuum packaging of refrigerated meat can extend the shelf life three to five times compared with that obtained in air.[62,112] However, for meat with a high pH, for example DFD beef (dark firm dehydrated beef) or poultry, the extension of shelf life is smaller,[26,46,107] and is only about twice that obtained in air.[62]

Vacuum packaging is applied mostly for primal cuts in wholesale storage, and only occasionally for display packs, most frequently for poultry. When discussing vacuum packaging, the relative importance of carbon dioxide inhibition in relation to oxygen limitation is important. It is easy to jump to the conclusion that oxygen is the key factor, just because the product normally is spoiled by aerobes.[119] However, with respect to *Pseudomonas* and meat, the following facts must be held in mind: (1) species of *Pseudomonas* are sensitive to carbon dioxide and their growth is significantly retarded by only a few percent of carbon dioxide in the gas phase (Figure 10-2); (2) the meat packages are stored at refrigeration temperatures where the gas solubility is high; and (3) *Pseudomonas* has a high affinity for oxygen, ie, the organism can grow at relatively low partial pressures of oxygen.[41,107,109] Ingram[82] concluded that "a large, even major, part of the inhibition in an impermeable wrap might be due *not* to lack of oxygen but to an increased concentration of carbon dioxide" (see Figures 10-4 and 10-7).

Conversely, the oxygen content is far from unimportant. Under atmospheres with an increased partial pressure of carbon dioxide, where bacteria sensitive to carbon dioxide have been inhibited, the oxygen content will affect the composition of the

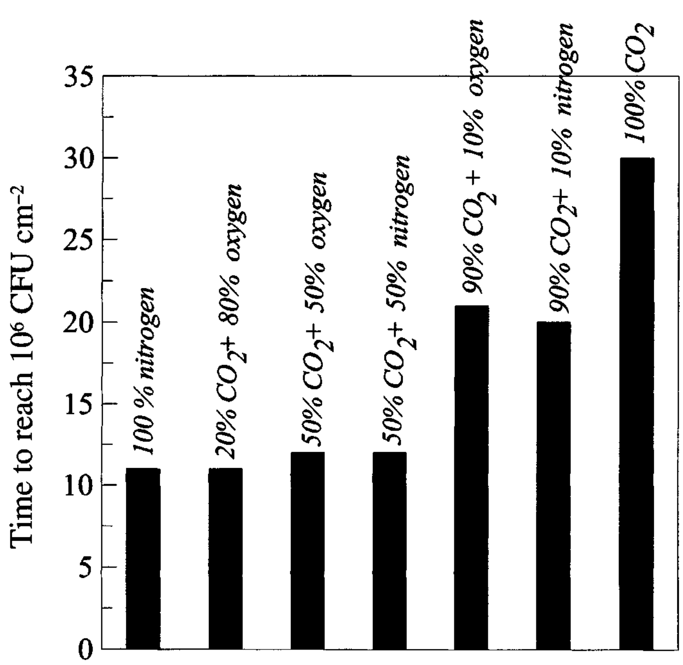

Figure 10-4 The Effect of Initial Gas Atmosphere on the Time To Reach an Aerobic Count of 10^6 Cell Forming Units (CFU) cm^{-2} on Pork (with bones) Stored at 4°C. The pork had an initial bacterial load of about 10^2 CFU cm^{-2} and was packed in gas-tight, aluminum-laminated pouches with an initial head space of approximately twice the volume of the product. *Source:* Copyright © 1989, Göran Molin.

secondary flora (Tables 10-1 and 10-2). Furthermore, oxygen can also affect end-product formation in a negative direction (ie, production of compounds with adverse effects on product quality).[11,149]

10.4.3 Packing in Modified Atmosphere with a Head Space

Packages designed with a head space containing a modified composition can be used for both display and bulk packaging. The proportions of oxygen and carbon dioxide can be selected either (1) to obtain a limited shelf life of meat and retain a desirable color or (2) for a maximal prolongation of shelf life without any major considerations about the meat color. The former is mostly used for display packaging and the latter for bulk packaging.

The color of raw meat is to a high degree dependent on the oxidation state of myoglobin.[59] The biological role of myoglobin is to carry oxygen, and the oxygenated myoglobin (oxymyoglobin) is bright red. This is the color most commonly associated with freshness because the consumer is accustomed to the appearance of meat exposed to the oxygen of the air. The oxygenation is rapidly reversible with

Table 10-1 Taxa Dominating the Aerobic Count of Pork Loins Stored at 4°C in Different Initial Gas Atmospheres, When the Count Had Reached the Level of about 10^6 CFU cm^{-2} of Meat Surface

Gas Atmosphere [% (v/v)]	*Dominating Taxa*
air	*Pseudomonas*
100% nitrogen	*Enterobacteriaceae*
20% CO_2 + 80% nitrogen	*Enterobacteriaceae* + *Aeromonas*
20% CO_2 + 80% oxygen	*Brochothrix thermosphacta*
50% CO_2 + 50% nitrogen	*Enterobacteriaceae* + *Brochothrix thermosphacta*
50% CO_2 + 50% oxygen	*Brochothrix thermosphacta*
90% CO_2 + 10% nitrogen	lactobacilli*
90% CO_2 + 10% oxygen	lactobacilli* + *Brochothrix thermosphacta*
100% CO_2	lactobacilli*

Note: The time required to reach 10^6 CFU cm^{-2} of meat surface is shown in Figure 10-4.[112]

*Mainly taxa within the genus *Lactobacillus* of the phenotypes described by Shaw and Harding[137] and Borch and Molin,[12] but the count may also include taxa of the genera *Leuconostoc* and *Carnobacterium*.[12,23,137] *Carnobacterium* has, from the taxonomic perspective, no close relationship with *Lactobacillus* and *Leuconostoc*.[21]

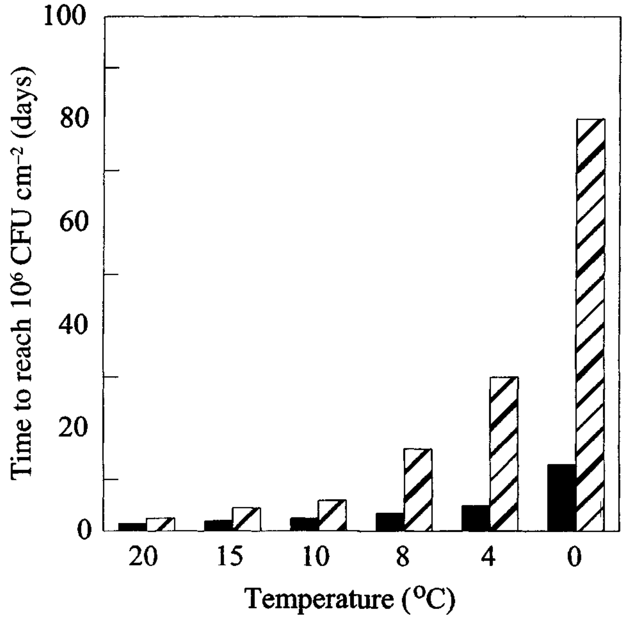

Figure 10-5 The Effect of Temperature and Carbon Dioxide on the Time Required for the Aerobic Count on Pork Loins To Reach to 10^6 CFU cm^{-2} on the Meat Surface. The head space at the time of packaging was equal to four times the volume of the product.[112] Initial head space air (filled columns), initial head space 100% carbon dioxide (hatched columns). *Source:* Copyright © 1989, Göran Molin.

changes in the partial pressure of oxygen; at low partial pressures the meat color darkens due to the purple color of the deoxygenated myoglobin. The time taken for myoglobin to turn to oxymyoglobin when exposed to air is 0.5 to 1 hour.[136] However, this change takes longer if the meat has been exposed to high concentrations of carbon dioxide (4 to 5 hours).[135]

On the other hand, myoglobin can also be oxidized, particularly at reduced partial pressures of oxygen, and can form metmyoglobin, ie, in the active site of the myoglobin molecule Fe^{2+} is oxidized to Fe^{3+} and the pigment turns brown.[59] This oxidation is only slowly reversible by enzyme-mediated metmyoglobin reduction, and the reduction capacity is limited and decays during storage.[50,59] Thus, in air-stored meat the color change due to metmyoglobin to some degree reflects lack of freshness of the meat. Deoxygenated myoglobin is more susceptible to oxidation than oxymyoglobin, thus an atmosphere with a low partial pressure of oxygen not only changes the meat color due to the color of the deoxygenated myoglobin, it also enhances the formation of metmyoglobin.[50]

If the color is important, as in a display package, the meat can be packed in an atmosphere of 70% to 80% (v/v) oxygen (to ensure a fresh red color) and 20% to 30% carbon dioxide in order to obtain a reasonable shelf life. This type of package gives a shorter shelf life than vacuum packaging[23,52,138,149]; but provides a shelf life about twice that of storage in air.[138]

To ensure a long shelf life the modified atmosphere should provide as high a partial pressure of carbon dioxide as feasible. As seen in Figure 10-4, (1) the slowest bacterial multiplication was obtained in 100% carbon dioxide, (2) the differences between growth rate in 20% (v/v) carbon dioxide and in 50% carbon dioxide is relatively small, and (3) it is of little consequence for the increase in the aerobic count whether or not an atmosphere of 50% carbon dioxide (or more) is supplemented with oxygen or nitrogen.

Metmyoglobin formation increases in meat stored in a modified atmosphere with a high amount of carbon dioxide for at least two reasons: (1) a reduced partial pressure of oxygen increases metmyoglobin formation; the formation is optimal at 0.1–1.3 kPa in a chemically defined system,[58] and optimal between 0.7–2.7 kPa for beef stored at 0°C[95]; and (2) the shelf life is extended and so, therefore, is the time available for metmyoglobin formation.

In bulk packs of meat, the color might be of lesser importance and the composition of the gas phase can be chosen for purely bacteriological reasons. In this case, the best results are obtained with pure carbon dioxide (Figure 10-4). The question of the color does not apply in poultry and is less pronounced in pork than in beef, therefore, for these products 100% carbon dioxide is preferable. Often there are problems in achieving a sufficiently long shelf life for fresh poultry.[107]

The high water solubility of carbon dioxide may sometimes be a problem in some modified atmosphere packages where it may lead to such a decrease in gas volume as to cause collapse of the package. This can be avoided either by incubating the product in the specific gas atmosphere prior to packing or by including nitrogen in the gas mixture. However, the concentration of carbon dioxide in the gas phase should, for microbiological reasons, initially be at least 70% (v/v).

The composition of the atmosphere in a package will change during storage, not only due to the carbon dioxide solubility, but also due to biological activity of both the meat and the microflora. The magnitude of such changes will be greatest in packs with a low ratio of the head space to meat volume. In practice the head space should be at least twice that of the product volume to ensure a reasonably stable composition of the gas atmosphere.[62]

If meat, eg, pork loins, is stored at a temperature close to the freezing point and in pure carbon dioxide, a shelf life of several months can be achieved (Figure 10-5).[9]

10.4.4 Microbial Flora

Figures 10-4 and 10-5 do not reveal whether different gas mixtures influenced the composition of the bacterial flora. The proportions of carbon dioxide and oxygen not only influence the rates of increase of the total numbers of bacteria, but also control the types of bacteria that dominate the flora and that presumably spoil the meat.[23] The dominant groups of bacteria when the "aerobic count" reaches about 10^6 CFU cm^{-2} of meat surface of the pork loins, shown in Figure 10-4, are indicated in Table 10-1. Similar results have been shown by others.[9,45,46,106,122]

The microflora in vacuum packages mimic the situation in modified atmosphere packages; poor packages with low carbon dioxide concentrations result in spoilage by enterobacteriaceae and *Aeromonas* while lactobacilli dominate the microflora of effective vacuum packages. However, a vacuum package is unsuitable for the storage of high-pH beef. The meat in these packages is often spoiled by enterobacteriaceae and *Aeromonas*, which is able to produce hydrogen sulfide[25,26] and some lactobacilli that under these conditions are able to form hydrogen sulfide.[37] The changes in the composition of the flora influence the eating quality of the meat and, hence, the shelf life. From a microbiological point of view, the optimal gas atmosphere for refrigerated meat is pure carbon dioxide, but after storage for a prolonged period in 100% carbon dioxide, the surface of the meat may acquire a porous gel structure.[62]

10.5 THE USE OF MODIFIED ATMOSPHERES IN PRESERVATION OF FRESH FISH

10.5.1 Spoilage

The microbial flora of fresh fish is heterogeneous, and, for example, includes the following: *Acinetobacter*, coryneforms, *Cytophaga, Flavobacterium, Micrococcus, Psychrobacter* (former "*Moraxella*-like"), *Aeromonas, Shewanella,* and *Pseudomonas*.[79,113,114,146,154] The initial numbers of bacteria on fish are normally higher than on mammalian meat. The living fish harbors bacteria on the skin (10^3–10^5 cm^{-2}),[79] gills (10^3–10^4 g^{-1} [79]) and in the intestines (up to 10^9 g^{-1} [79]), and even after filleting the count is often close to 10^5 CFU cm^{-2}.[109,113,146,154]

The high initial numbers of bacteria shorten the shelf life and result in a more complex bacterial flora after storage. The pH of fish tissue is usually relatively high (6.2–6.5), allowing rapid bacteriological spoilage. In spite of this, the microflora reaching high numbers in a particular batch of fish will be relatively homogeneous.[114]

The dominant groups of bacteria on fish stored under refrigeration are *Pseudomonas* (mostly *Pseudomonas fragi* and *Pseudomonas fluorescens*) and *Shewanella putrefaciens*, and to a lesser extent *Aeromonas* and *Psychrobacter*[79,145] (Figure 10-6).

Fish from warmer waters often harbor a higher proportion of Gram-positive bacteria[79] than those from colder waters and, due to the lower numbers of psychrotrophic bacteria, the shelf life at refrigeration temperatures is generally longer.[16,140] The similarities in the spoilage flora of fish and of mammalian meat are obvious but there is also, at least, one striking difference, ie, a substantial part of the fish flora consists of *Shewanella putrefaciens*.[145] This causes a problem because *S. putrefaciens* produces a spec-

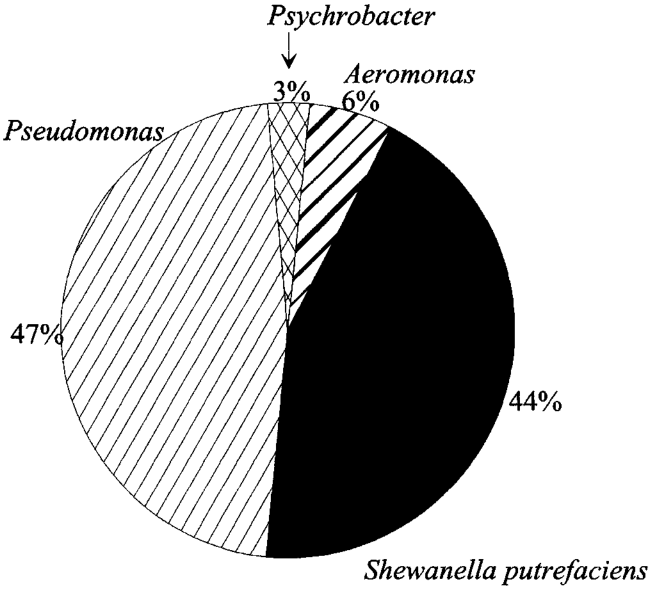

Figure 10-6 The Distribution of Different Bacterial Taxa Dominating the Flora of Swedish Fish Fillets When the Aerobic Count Approached 10^8 CFU g^{-1} after Storage in Air. The fillets had been stored at 2° to 8°C and represented a wide variety of different fish species.[145] The *Aeromonas* were all isolated from fish originating from Swedish inland waters.

trum of end-products during growth that are extremely deleterious to eating quality. Some of these can also be produced by *Pseudomonas*, for example, but the deleterious abilities are especially pronounced for *S. putrefaciens*, which produces hydrogen sulfide and also reduces trimethyl-amine-oxide, present in most marine fish, to trimethyl-amine[93,96]; the latter provides the product with an offensive spoiling fishy smell and the former with a putrid odor.[79] A factor causing problems with packaging in modified atmospheres is that *S. putrefaciens*, compared with *Pseudomonas* and enterobacteriaceae, is relatively resistant to carbon dioxide.[113,154] Occasionally *S. putrefaciens* also causes problems on mammalian meat; a typical situation is spoilage due to hydrogen sulfide formation in vacuum packed beef of high pH.[63] pH is a powerful controlling factor for the microflora at low temperatures; *S. putrefaciens* and *Aeromonas* particularly are less competitive at pH below 6.[23,26,61]

Furthermore, *Shewanella putrefaciens* is a heterogeneous species and the typical strains found growing on fish comprise at least two distinct groups. Both differ considerably from the type strain of *Shewanella putrefaciens*.[145,151] Clinical isolates designated as *S. putrefaciens* seem to a high degree to be misidentified and are, instead, *Shewanella alga*.[122] *Photobacterium phosphoreum*-like bacteria may grow and cause problems on fish stored in modified atmosphere.[27]

10.5.2 Modified Atmosphere

The general effect of carbon dioxide on the increase of the aerobic count of fish (Figure 10-7) is similar to that on mammalian meat (Figure 10-4). The increase in numbers was similar whether or not the carbon dioxide was supplemented with oxygen or nitrogen. The effect of the gas atmosphere on the proportion of *Shewanella putrefaciens* is of special interest because of the deleterious effect of this bacterium. The effect of the initial composition of the gas phase on the proportions of *S. putrefaciens* and lactobacilli in the aerobic count on fish is shown in Table 10-2.

Increased concentrations of carbon dioxide reduced the proportion of *S. putrefaciens* in the flora, but the effect was much less than that on *Pseudomonas*. The proportion of *S. putrefaciens* was lowest in either pure carbon dioxide or 10% (v/v) oxygen in 90% carbon dioxide (Table 10-2), but the growth-retarding effect was greater in 100% carbon dioxide (Figure 10-7). Nevertheless, from the microbial point of view, it is better to mix carbon dioxide with oxygen than with nitrogen when it comes to packaging fresh fish in modified atmosphere. The apparent stimulating effect of oxygen on the proportion of lactobacilli in the flora (and the coincident retarding effect on the proportion of *S. putrefaciens*) might be due to the ability of many lactobacilli strains to produce H_2O_2 in the presence of oxygen.[13]

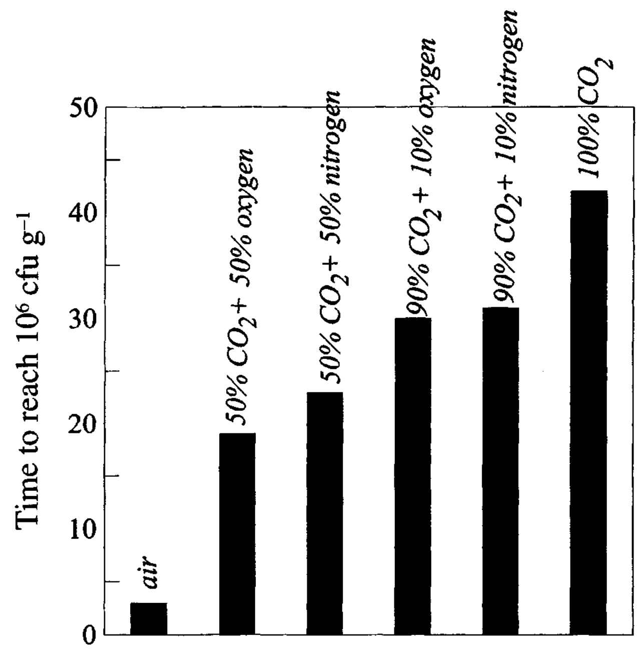

Figure 10-7 The Effect of Initial Gas Atmosphere on the Time To Reach an Aerobic Count of 10^6 Cell Forming Units (CFU) g^{-1} of Cod Fillet Stored under Atmospheric Pressure and at 2°C. Fillets were enclosed in glass jars and the head space was equal to six times the volume of the product. *Source:* Reprinted with permission from I.M. Stenstrom, Microbial Flora of Cod Fillets Stored at 2°C in Different Mixtures of Carbon Dioxide and Nitrogen/Oxygen, *Journal of Food Protection*, Vol. 48, pp. 585–589, © 1985, International Association of Milk, Food and Environmental Sanitarians, Inc.

10.5.3 Temperature

In comparison with mammalian meat, the shelf life–prolonging effect of packaging fish in modified atmosphere is less pronounced. This is due probably to the presence of *S. putrefaciens* on the fish (Table 10-2). It is particularly important to combine the modified atmosphere with a low refrigeration temperature. This is shown for herring fillets in Figure 10-8, and similar results have been presented by others.[31,129,142]

Table 10-2 The Effect of Initial Gas Atmosphere on the Proportion of *Shewanella putrefaciens* and Lactobacilli of the Aerobic Count of Cod Fillets Stored at 2°C, When the Count Had Reached about 10^6 CFU g^{-1} of Fish Tissue

Initial head space air (filled columns) or 100% carbon dioxide (hatched columns). *Source:* Reprinted with permission from G. Molin and I.M. Stenstrom, Effect of Temperature on the Microbial Flora of Herring Fillets Stored in Air or Carbon Dioxide, *Journal of Applied Bacteriology*, Vol. 56, pp. 275–282, © 1984, Blackwell Science, Ltd.

Although at relatively high refrigeration temperatures, the retarding effect of pure carbon dioxide is clear (Figure 10-8), the controlling effect on the microflora is much less at higher temperatures, ie, the proportion of *S. putrefaciens* is high and true shelf life is considerably shorter than that depicted by the aerobic count (Table 10-3). The proportion of *S. putrefaciens* decreases with increasing concentration of carbon dioxide (Table 10-2) and decreasing temperature (Table 10-3). Thus, it is clear that *S. putrefaciens* is relatively resistant to carbon dioxide but is inhibited by a combination of low temperature and high carbon dioxide concentration.

10.5.4 Practical Considerations

The bacterial load of fish depends on the freshness of the product. The time to reach a certain number of bacteria does not necessarily determine the true shelf life of the product. This depends on odor and flavor of the fish and is often shorter than the shelf life indicated by the bacterial numbers.[27,75] Nevertheless, the shelf life can be extended by increased levels of carbon dioxide.[31,101,129,130,142]

Shelf life, of course, varies between different fish species and depends on how the fish is handled from the time of catching.[79] Using Norwegian cod as an example, the shelf life in air for this product is normally about 8 days at 0°C.[144] The following are crucial for the quality and shelf life: (1) the cod is gutted and deblooded as quickly as possible, and (2) it is rapidly cooled to 0°C.[144] A system based on modified atmosphere in consumer packs was developed for this product, and is shown schematically in Figure 10-9.[144]

Before packaging, the fillets were dipped in 20% (w/v) chilled salt (NaCl) solution for 12–14 seconds (Figure 10-9). The dipping resulted in a salt concentration of about 1% in the fillets (but no apparent salty taste). The salt dip reduced the drip in the package and also cooled down the fillets before packaging. The modified atmosphere package makes cooling difficult. The system provided a shelf life of the cod of 14 days from catching to consumption.[144] The cod fillets (250–350 g) were packed in an atmosphere of 50% (v/v) CO_2 and 50% O_2 in a flexible package with a volume of 750 cm^3 (package machine, Multivac R 7000; laminate, PVC/PE).[144] It is recommended that the ratio of product to package volume be 40% or be-

low. A higher concentration of carbon dioxide was not used because the package would deflate due to the water solubility of the carbon dioxide.

10.6 THE USE OF MODIFIED ATMOSPHERES IN PRESERVATION OF PROCESSED MEATS

10.6.1 General

The expression "processed meats" includes a wide variety of different products, not always within stringent borderlines. The group includes traditional cured meats such as bacons, sausages, and hams, and also convenience food products such as premade hamburgers and meatballs. Especially important factors to consider are whether the product has been heat treated, the concentration of NaCl, and the water activity. The products that provide different environments for spoilage microorganisms and rely on different preservation systems will not be discussed in detail in this section. Instead, some general principles that have relevance for most of the products will be discussed. However, there can be special conditions for specific products that can overrule some of the general principles.

10.6.2 Raw Cured Meats

The storage of raw, cured meats in modified atmospheres differs from that of fresh meat primarily because of the controlling effect of NaCl on the spoilage flora. Thus, at low temperatures, about 3% NaCl will reduce both the growth rate of the spoilage flora

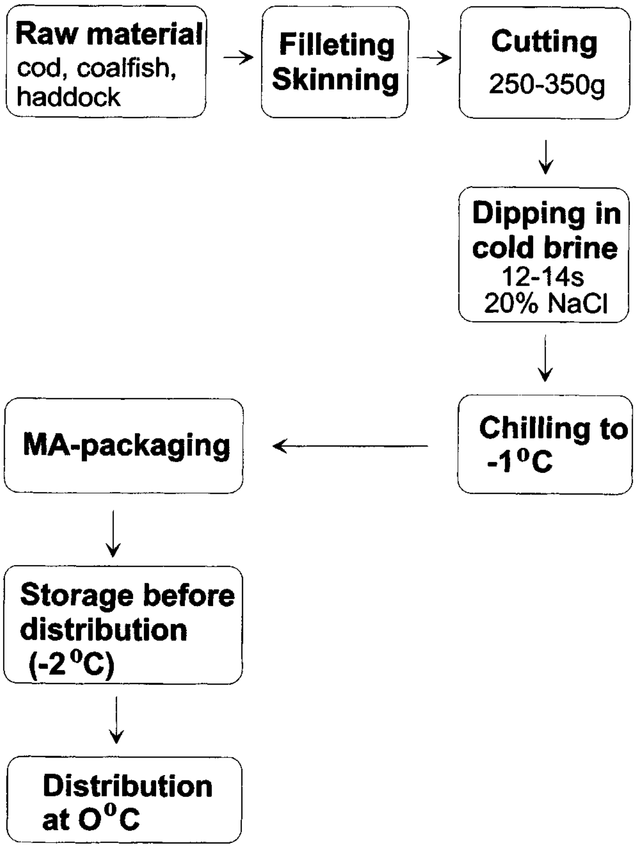

Figure 10-9 A System for Production of Retail Packs of Norwegian Cod Fillets in Modified Atmosphere (50% CO_2 and 50% O_2)

and the proportion of *Pseudomonas* with respect to *Brochothrix thermosphacta*.[9] This effect will be in addition to that of the modified atmosphere, and long shelf lives can be obtained with the combination of low temperature, high carbon dioxide concentrations, and NaCl (3% NaCl).[9] The flora under these conditions is dominated by lactobacilli.[9] If additional growth-restricting factors are added to that of NaCl, or if the NaCl concentration is increased, for example, to decrease the water activity to 0.94, the effect of carbon dioxide on the increase in "aerobic count" will diminish.[7] This is because the environmental selection pressure on the spoilage flora is optimal for lactobacilli, and the growth rate for this group is close to its minimum. If the environment is made even more hostile, the growth of lactobacilli will stop completely.[7] If these types of product are stored in air, they will be overgrown by yeasts, and if the water activity is decreased further, by molds.[7,112] Molds are easily eliminated by storage in strictly oxygen-limited atmospheres and yeast growth may be substantially reduced.[7,112]

10.6.3 Heated Cured Meats

Heated cured meats such as frankfurter sausage or smoked pork loin differ from fresh meat or fish in the following respects:

1. The mammalian cells do not metabolize and neither consume any oxygen nor produce any carbon dioxide. Only the microflora consumes oxygen and releases carbon dioxide. These activities proceed slower in a package of processed meat than in packages of fresh meat or fish.[10]
2. The processing has changed the microbiological flora, ie, taxa such as *Pseudomonas*, *enterobacteriaceae*, *Shewanella*, and *Aeromonas* have been eliminated, or greatly reduced in numbers by the heat process, and post-process contaminants of these groups have severe difficulties in growing; *Brochothrix* has difficulties in competing.[10,12,14] This leads to a prolongation of shelf life even in air, where the growing microflora mostly will be dominated by yeasts (or, if the water activity is low enough, by molds).[112] Thus, if the shelf life must be further extended, the products can be vacuum packed or gas packed.

Vacuum Packaging

By vacuum packaging of, for example, emulsion sausages, the growth of yeasts is reduced, or prevented, and the dominant microorganisms are homofermentative *Lactobacillus* species.[12,14] Also substantial numbers of *Leuconostoc* and *Carnobacterium* can be found.[12]

The effect of storage temperature on the increase of aerobic count in vacuum packed emulsion sausage is shown in Figure 10-10. The spoilage of sausages is not directly linked to the bacterial numbers.[91] The flavor can be acceptable long after the total count has reached its maximum,[14] but before the sausages take on an offensive odor or taste, they become unacceptable due to slime formation; no slime is visual before the total count has exceeded 10^6 CFU g^{-1}.[14,53]

Gas Package with a Head Space

A major drawback of vacuum packing is that the product gets a wet surface. This reduces the acceptability of the product but has also bacteriological implications, eg, the product is more likely to become slimy. A gas package with a substantial head space can provide the product with a dryer surface, and less drip (free meat juice in the package). However, there must be nitrogen in the gas because with pure carbon dioxide the product will still exude water.[10,14]

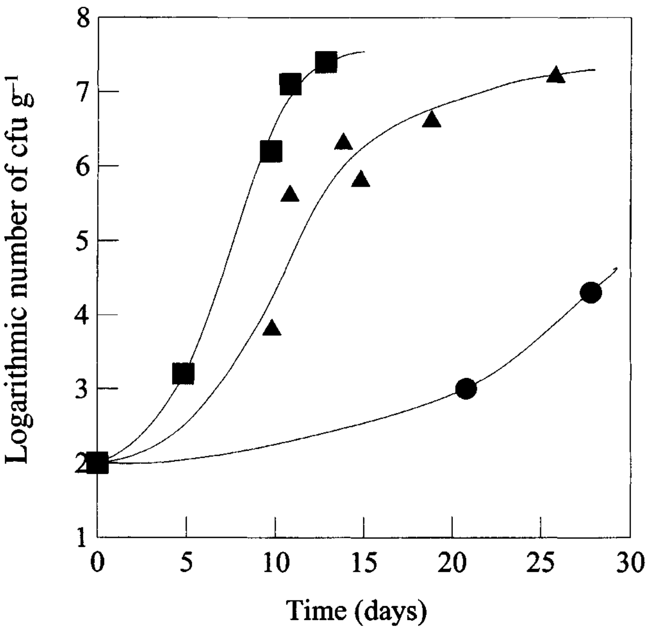

Figure 10-10 Increase in Aerobic Count on Vacuum Packed Emulsion Sausage Stored at Different Temperatures (Swedish Falukorv[12]). Filled squares indicate storage at 8°C, filled triangles indicate 4°C, and filled circles indicate 0°C. *Source:* Copyright © 1989, Göran Molin.

Packaging emulsion sausages in pure nitrogen resulted in a longer shelf life than packaging in pure carbon dioxide, ie, the time until the flavor deteriorated and slime was detected was longer in nitrogen than in pure carbon dioxide.[14] No advantages or disadvantages in respect to shelf life were seen with carbon dioxide concentrations up to 50% (v/v) in nitrogen.[14] However, the addition of a certain amount of carbon dioxide (20% to 40%) in the nitrogen can be a hurdle for yeast or mold development in packages where some oxygen is present by, for example, accidental leakage.

Oxygen should be avoided in packages for heated, cured meats for at least the two following reasons: (1) oxygen enables the growth of molds and encourages growth of yeasts and (2) oxygen helps many lactobacilli to produce more adverse end-products, eg, H_2O_2, acetic acid, formic acid, and acetoin/diacetyl.[11,14] Hydrogen peroxide causes green discoloration.[53]

The recommended gas mixture for packaging heated, cured meats in modified atmosphere is 20% to 40% (v/v) carbon dioxide in 60% to 80% nitrogen.

10.7 THE USE OF MODIFIED ATMOSPHERES IN PRESERVATION OF OTHER FOODS

10.7.1 Milk and Cheese

Raw milk is mainly spoiled by *Pseudomonas fluorescens* biovar 1, *Pseudomonas fragi, Pseudomonas lundensis,* and *Pseudomonas fluorescens* biovar 3.[152] If the milk was pasteurized, about half of the packed milk is spoiled under refrigeration by the same taxa of Gram-negative bacteria. The other half is slowly spoiled by *Bacillus* species.[152] The bacteriological shelf life of refrigerated milk can be prolonged by applying an increased partial pressure of carbon dioxide[92] (see Chapter 22).

In cheese, the manufacturing process has suppressed the spoilage flora of fresh milk, and normally the major threat is yeasts and molds on the surface. They can be suppressed by a modified atmosphere containing low oxygen levels and increased carbon dioxide concentrations.[48,103] Vacuum packaging occasionally fails to protect against molds[81] (see Chapter 22).

10.7.2 Bread

Bread can be packed in vacuum or modified atmosphere in order to delay staling[3] or to hinder the growth of molds,[100] eg, 70% to 80% (v/v) carbon dioxide and 20% to 30% nitrogen.

10.7.3 Fruits and Vegetables

The rate of respiration of fruits and vegetables can be reduced by raising the partial pressure of carbon dioxide and decreasing the partial pressure of oxygen. However, a too high level of carbon dioxide will result in tissue damage, similar to that caused by too low temperatures.

Several processes in vegetables and fruits other than respiration are influenced by the gas atmosphere, eg, ripening, production of ethylene, breakdown of chlorophyll, and structural changes due to the breakdown of pectin. These processes are different for different products, eg, between apples and pears.[56] Thus, the design of controlled or modified atmospheres is different for different types of vegetables and fruits.[120] Apples can be stored in a mixture of 5% to 10% (v/v) carbon dioxide and about 3% oxygen and nitrogen as the filler; tomatoes can be kept in an atmosphere of 3% to 9% carbon dioxide, 3% to 9% oxygen and nitrogen[55]; and a suitable atmosphere for strawberries is 10% to 20% carbon dioxide, with a low oxygen concentration and nitrogen as a filler.[17,71]

Storage of fruits and vegetables in modified atmospheres is done to retard the ripening of the product, and to reduce quality losses during storage. The latter includes microbiological spoilage by Gram-negative bacteria such as *Pseudomonas* and *Enterobacteriaceae*, and by fungi.[90] However, the carbon dioxide concentrations are relatively low and even if *Pseudomonas* and several fungi are relatively sensitive to carbon dioxide, the microbiological aspects of storage of vegetables and fruits in modified atmospheres are mostly of secondary importance.

10.8 SOME SAFETY ASPECTS OF MODIFIED ATMOSPHERES

10.8.1 *Clostridium botulinum*

Consideration of safety aspects of packaging foods in modified atmospheres started with the fear that vacuum packaging could increase the hazards of botulism, ie, that the anaerobic conditions in a vacuum package could facilitate growth and toxin formation by *Clostridium botulinum*.[28,57,82] Furthermore, it could be argued that vacuum packaging, or even more so, modified atmosphere packaging with a high partial pressure of carbon dioxide, increases the shelf life of a product to such an extent that there is more time available for growth and toxin production by *C. botulinum* to occur. These problems might be especially pronounced in connection with individual retail packages where the chance of temperature abuse is more pronounced than at the supplier level.[57] However, the fears for growth and toxin formation of *C. botulinum* in refrigerated foods packed in modified atmospheres seem to be exaggerated.

First, irrespective of the gas atmosphere surrounding the piece of meat or fish, the conditions are anaerobic enough for growth of *C. botulinum* a few mm below the tissue surface[5,82] or below a metabolizing biofilm of microorganisms.

Second, *C. botulinum* is not alone in these types of products. It has to compete with a spoilage flora that either will be dominated by taxa that severely affect the eating quality or by a dominating fraction of lactobacilli (see above), which are well known for their ability to suppress clostridia.[29,30,85]

Third, even though increased partial pressures of carbon dioxide have been shown to stimulate the germination of clostridia spores,[40,49] a modified atmosphere of 100% carbon dioxide suppressed toxin production by *C. botulinum* in comparison with 100% nitrogen.[34] No difference in growth rates of *Clostridium perfringens* were found between 100% carbon dioxide and 100% nitrogen,[126] while Mead[107] reported that the growth of *C. perfringens* was retarded by carbon dioxide.

In conclusion, the earlier presumed hazards for growth and toxin formation by clostridia in refrigerated meats and fish packed in modified atmospheres seem exaggerated. Most products are judged inedible well before any toxin of *C. botulinum* can be found in the products. This general conclusion was also drawn by others.[82,107]

10.8.2 Psychrotrophs with Pathogenic Potential

In the safety discussion concerning clostridia, it is important to remember that most clostridia are unable to grow at chill temperatures. Those able to do so, such as psychrotrophic strains of *Clostridium botulinum*, grow only poorly under these conditions, ie, they are unable to grow below 3°C.[131] However, there are also psychrotrophs with considerable pathogenic potential that can reach high numbers in refrigerated foods, for example, *Listeria monocytogenes*, *Aeromonas* species,[98,118,145] and *Yersinia enterocolitica*.[84,88,94] There might also be other species of the family enterobacteriaceae to consider, for example, *Citrobacter freundii* and *Enterobacter cloacae*.[97] Another potential threat, in refrigerated fish, might be *Vibrio* species.[98]

The Gram-negative bacteria occasionally occur as a significant part of the spoilage flora of refrigerated fresh meat (*Aeromonas* and enterobacteriaceae) and fish (*Aeromonas*, enterobacteriaceae, and *Vibrio*) stored in air or in modified atmospheres. Certain environmental parameters are beneficial for their development. For example, a high pH is beneficial for *Aeromonas*[124] and *Yersinia enterocolitica*[134] and a somewhat higher refrigeration temperature would be beneficial for the enterobacteriaceae.[8,33] Furthermore, a modified atmosphere with a relatively low partial pressure of carbon dioxide can favor the development of enterobacteriaceae and *Aeromonas*[33,66] (Tables 10-1 and 10-2). The best protection against *Aeromonas* and enterobacteriaceae is offered by the combination of low storage temperature and a modified atmosphere that provides a high partial pressure of carbon dioxide.[33]

10.8.3 *Listeria monocytogenes*

Listeria monocytogenes is not likely to compete successfully in refrigerated raw meat and fish.[47,66] Theoretically, a hazard may arise in modified atmosphere packs after extended storage periods, at moderate partial pressures of carbon dioxide, and in the presence of oxygen.[101,139,157] Another important parameter is the pH, ie, a pH below 5.0 will decrease substantially the likelihood for growth of *L. monocytogenes*.[47,69]

However, the problem with *L. monocytogenes* is more connected to products that are consumed directly without heat treatment and in products where the normal spoilage flora has been inhibited.[47] The modified atmosphere might eventually increase the hazards due to extended storage times. In general, a high partial pressure of carbon dioxide in combination with a low storage temperature will decrease the chances for growth of *L. monocytogenes*.[47,66] For example, the growth in cottage cheese is stopped by packaging in elevated concentrations of carbon dioxide.[19,48] Furthermore, the chances of *L. monocytogenes* growth decreases if the domination of lactobacilli in the product is strong.[47]

The possibility of growth of *L. monocytogenes* is relatively higher in, for example, some soft cheeses and in some vegetables,[47,121] and may be higher in preprepared salads packed in modified atmosphere with only a low concentration of carbon dioxide. Vegetables are seldom stored in atmospheres exceeding 10% (v/v) carbon dioxide. In the case of cheese, the chances of growth of *L. monocytogenes* can be decreased by packaging in modified atmospheres containing a high partial pressure of carbon dioxide.[19,48]

10.9 CONCLUDING REMARKS

Carbon dioxide is the most powerful gas component in modified atmosphere packaging to inhibit microbial growth. Growth inhibition increases with increase in the partial pressure of carbon dioxide and low temperature reinforces the growth-inhibitory effect.

The composition of the spoilage flora of refrigerated meat is controlled by the gas atmosphere according to the following principles:

1. *Pseudomonas*, which dominates the spoilage of meat stored in air, is retarded at a partial pressure of carbon dioxide of about 10 kPa (10% [v/v]) in the gas phase at atmospheric pressure).[54,109]
2. *Brochothrix*, enterobacteriaceae, and to some degree also *Aeromonas*, are the first to take over in atmospheres where *Pseudomonas* has been inhibited due to an increased carbon dioxide concentration[26,46,112] (Table 10-1).
3. *Brochothrix* is slightly more resistant to carbon dioxide than members of the enterobacteriaceae, but has a much slower growth rate under anaerobic conditions and is, because of this, outnumbered by enterobacteriaceae in an anaerobic environment. On the other hand, in the presence of oxygen *B. thermosphacta* will dominate due to its higher resistance to carbon dioxide.[23,26,46,112]

4. The growth of both enterobacteriaceae and *Brochothrix* is inhibited by partial pressures of carbon dioxide close to atmospheric pressure. The bacterial flora will instead be dominated by lactobacilli, primarily of the genus *Lactobacillus* but also substantial numbers of *Leuconostoc* and *Carnobacterium* can occur.[12,23,137]

Meat in modified atmosphere should preferably be stored at temperatures below 4°C.

One obstacle with modified atmosphere packaging of fresh fish is the growth of the relatively carbon dioxide–resistant *Shewanella putrefaciens*. The distribution of fresh fish, from the microbiological point of view, preferably ought to be performed at 0°C or below, and in a gas atmosphere of pure or nearly pure carbon dioxide. However, there can be considerations other than the microbiological ones, eg, the appearance of the product and the package, and the loss of water from the product. If the carbon dioxide is supplemented with another gas for reasons other than microbiological ones, it should be with oxygen. Nitrogen should be avoided in connection with fresh fish.

The partial pressure of carbon dioxide in modified atmosphere packaging of processed meat is less critical than for fresh meat. The growth of Gram-negative bacteria is retarded by factors such as NaCl and decreased water activity. The assignment of the modified atmosphere is to maintain a dry surface and keep out the oxygen; a suitable atmosphere is 20% to 40% carbon dioxide in 60% to 80% nitrogen. To ensure the absence of oxygen, an oxygen absorber can be included in the package.

The use of modified atmosphere packaging is increasing, and the packing technique and the control of the atmosphere within the package will most probably further improve in the future. Besides the effect on eating quality, it is equally important to consider the safety aspects of extended storage times. The longer the storage time, the greater the potential microbiological hazards. Sophisticated packaging systems for susceptible refrigerated foods must be combined with advanced systems for microbial control, founded on solid knowledge of microbial ecology of foods.

11.1 INTRODUCTION: OXIDATION-REDUCTION REACTIONS AND REDOX POTENTIALS

11.1.1 Background Theory

Oxidation of any substance (a *reductant)* is accomplished by loss of electrons. Thus, for example, when a Fe(II) ion is oxidized, it sheds an electron and is thus converted into a Fe(III) ion as follows:

$$Fe^{2+} \rightarrow Fe^{3+} + e^-$$

Yet for such an oxidation to occur, the electrons that are dispensed with must be accepted by some other substance, which thereby serves as an *oxidant.* Thus, the Fe(II) ion may have been oxidized by oxygen, which was in turn reduced to water:

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$

The overall process is a balanced oxidation-reduction reaction, represented as

$$4Fe^{2+} + O_2 + 4H^+ \rightarrow 4Fe^{3+} + 2H_2O$$

Every oxidation-reduction may therefore be viewed as the consequence of the necessary interaction of an electron-donating and an electron-accepting "half reaction." The electron-donating component constitutes one *redox couple* and the electron-accepting component, another. Ideally, every redox couple is fully reversible, so that all can be represented by the following general equation:

$$a(\mathrm{Ox}) + b(\mathrm{H}^+) + ne^- \rightleftharpoons c(\mathrm{Red})$$

where Ox represents the oxidant and Red is the reductant formed from it by the acceptance of electrons (and sometimes of protons also).

Of the two redox couples that participate in an oxidation-reduction reaction, it follows that one must be the more eager to accept electrons. It is therefore possible on this basis to construct a relative scale of *redox potentials* of these couples, the redox potential being a measure of the *intensity* of its tendency to accept electrons.[57] As with any such scale, it is first necessary to define a set zero value. This is decreed to be the redox potential of a standard hydrogen redox couple (also known as the standard hydrogen electrode or standard hydrogen half-cell), which consists of hydrogen gas at 1 atmosphere pressure in equilibrium with an aqueous solution of hydrogen ions at unit activity (ie, pH 0). Were a redox couple of unknown potential to be made one half-cell in an electrochemical cell in which this standard hydrogen electrode (SHE) formed the second half-cell, then the maximum electromotive force in volts displayed by this cell (ie, when no current was allowed to flow) would be a measure of the potential difference between the redox couple and the reference zero. This value will be the redox potential (E_h) of the redox couple at the prevailing temperature and pH. Couples displaying positive values of E_h are more oxidizing than the SHE in proportion to the magnitude of the voltage difference. Similarly, couples more reducing than the SHE will have negative redox potentials; the more negative, the more reducing is the couple.

How redox potentials are measured in systems of bacteriological and biochemical interest has been fully described,[3,4,28,34,36,38,41,61] and methods of measurement of redox potentials in meat[71] and wine[81] have recently been published. In brief, a highly polished platinum electrode, when introduced into the system, registers its redox potential and establishes a measured electromotive force (potential difference) when it is then suitably connected to a stable reference electrode. In practice, it would be rather inconvenient to attempt to employ a standard hydrogen electrode for this reference purpose, so one of several commercially available electrodes is used in its place.[34] The potentials of these standard electrodes, relative to the hydrogen electrode, are known over a range of temperatures. Thus, for example, if a reducing biological redox couple registered at 30°C a potential difference ΔE of 562 mV against a saturated calomel electrode (whose potential at 30°C is +242 mV), then the redox potential of the test couple on the hydrogen scale (ie, its E_h value at 30°C) is –320 mV for

$$\Delta E_h = E_h \text{ (oxidizing couple)} - E_h \text{ (reducing couple)}$$
$$562 = +242 - E_h \text{ test couple}$$
$$\text{where, } E_h \text{ test couple} = 242 - 562 = -320 \text{ mV.}$$

Alternatively, the redox potential of the test couple versus the saturated calomel electrode could be recorded as an E_{cal} value of –562 mV, in which case its redox potential on the hydrogen scale would be readily calculable as (–562 +242) mV = –320 mV.

An important consequence of the ability to measure the maximum electromotive force (ΔE_h in volts) that would be developed by the conjunction of two redox couples is that it is thereby possible to calculate the electrical work that would be performed by the oxidation-reduction reaction were it to operate thermodynamically reversibly and isothermally. This work equals $nF\Delta E_h$ J mol^{-1}, where n is the number of electrons "lost" per molecule of reducing agent oxidized (or the quantity of electricity flowing through the cell measured in Faradays), and F is the Faraday constant, which equals 92,487 J V^{-1} mol^{-1}. Because this work represents the loss in Gibbs free energy of the system per mol of reductant oxidized, then

$$-\Delta G = nF\Delta E_h \text{ J mol}^{-1}$$

This is an important relationship in that not only does it form the basis of a very practical way of deriving values of ΔG for oxidation-reduction reactions, but, by highlighting the proportionality between the degree of exergony (spontaneity of reaction) and the span of E_h difference between the electron-donating and electron-accepting couples, it justifies the attention that is paid to the assignment of E_h values to such redox couples.

11.1.2 Nature of the Redox Potential of a Redox Couple

Because the essence of oxidation-reduction is the transfer of electrons between participant couples, an analogy may be drawn with acid-base interactions with their transfer of protons. It is a small step thereafter to conceive of *electron activity* as the analogue of proton activity and of *pe* values (negative logarithm of electron activity) as the redox counterpart of pH values. Indeed, in soil science and agronomy, much use has been made of such *pe* values.[6] Yet even those that use the term concede that, under conditions relevant to biological systems, electrons do not exist as free entities in any phase (except in metals). Thus to conceive of electron activity in the same terms as proton activity is not only misleading but is actually wrong. It is also unnecessary, since the E_h values of redox couples, when reported together with the conditions (temperature and pH) under which they were measured, give all the information that is required without having to invoke the complication of proxy *pe* numbers. On the other hand, it is legitimate for thermodynamic purposes to define the electrochemical potential of the electron in terms of the electrochemical potentials of the oxidized and reduced species of the redox couple.[83] In particular, the standard redox potential of a couple ($E°$) is an expression of the standard chemical potential of its electron(s). Although in thermodynamic terms, $E°$ is the redox potential of the couple in its standard state (unit activities of participating species at 25°C, 1 atmosphere pressure [atm]) it can be shown that it is also the redox potential displayed by the redox couple when its oxidant and reductant components are present at equal concentration (activity), whatever this happens to be in absolute terms. It is for this reason that the symbol E_m (for midpoint potential) is frequently used in place of $E°$ to represent the standard redox potential of a redox couple in its 50% reduced condition (Figure 11-1). This midpoint potential is the standard potential about which the actual potential (E_h) can vary in proportion to the extent to which the ratio of oxidant to reductant differs from unity. The relationship is expressed in the following Nernst equation:

$$E_h = E_m + 2.303\frac{\mathrm{RT}}{n\mathrm{F}}\log\frac{[\mathrm{Ox}]}{[\mathrm{Red}]}$$

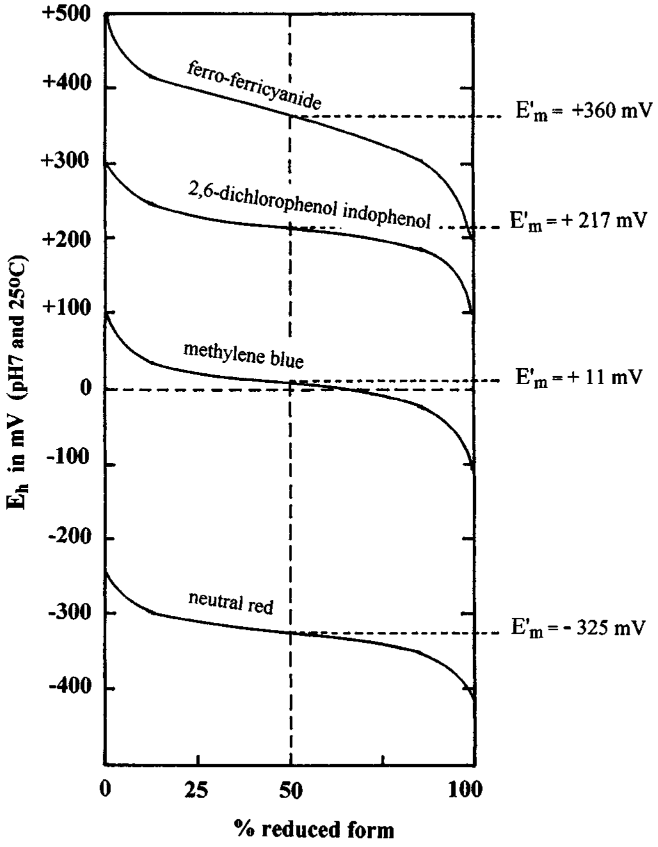

Figure 11-1 Relationship between the Redox Potential of a Redox Couple and Its Percentage Reduction. *Source:* Adapted with permission from J.G. Morris, *A Biologist's Physical Chemistry*, 2nd ed., pp. 322–359, © 1974, Edward Arnold.

At 30°C, the factor $2.303\mathrm{RT}/n\mathrm{F}$ is approximately equal to $0.06/n$ so that for a redox couple whose reductant loses two electrons when it is oxidized to the oxidant form, if when 50% oxidized its redox potential (E_m) was +100 mV, then when it was 99% in its oxidized form the potential (E_h) would be +160 mV, and when it was 99% in its reduced condition its E_h value would be +40 mV. Thus, for all intents and purposes, the working range of this $n = 2$ redox couple would be 120 mV.

11.1.3 Relationship between Redox Potential and pH

When protons are simultaneous participants in the operation of the redox couple, this can be represented in the form of the general equation given previously, ie,

$$a(\mathrm{Ox}) + b(\mathrm{H}^+) + ne^- \rightleftharpoons c(\mathrm{Red})$$

In these circumstances

$$E_h = E° + 2.303\frac{\mathrm{RT}}{n\mathrm{F}}\log\frac{[\mathrm{Ox}]^a[\mathrm{H}^+]^b}{[\mathrm{Red}]^c}$$

or,

$$E_h = E° + \frac{2.303\ \mathrm{RT}}{n\mathrm{F}}\log\frac{[\mathrm{Ox}]^a}{[\mathrm{Red}]^c} - 2.303\frac{b\mathrm{RT}}{n\mathrm{F}}.\mathrm{pH}$$

If unknown, the nature of the pH dependency of the couple can be deduced from plotting measured values of E_h against pH over the pH range of interest, when the slope of the line will equal $-2.303\ b\ (\mathrm{RT}/n\mathrm{F})$. If $b/n = 1$, then the slope $\Delta E_h/\Delta\mathrm{pH}$ will approximately equal 60 mV at 30°C. That is, the E_h will change by approximately 60 mV for every unit of pH change. Some E_h/pH relationships are complicated by the fact that the slope of the plot may change over various portions of the pH range. Indeed, there might be one part of the pH range in which E_h is independent of pH (when the plotted line will have zero slope) indicating that in this pH range there is no participation of protons in the redox couple (Figure 11-2). As noted previously, it is therefore essential to specify not only the measured E_h value, but also the pH at which it was determined (as well as the temperature).

In an attempt to avoid having always to record both E_h and the prevailing pH, Clark and his colleagues in the 1920s introduced the concept of *rH*. The reasoning was that if the pressure of hydrogen gas that would be in equilibrium with the redox couple were recorded, this would automatically accommodate any change in pH as well as E_h (and *rH* was suggested as most suitable for this purpose, being defined as the negative logarithm of the equilib-

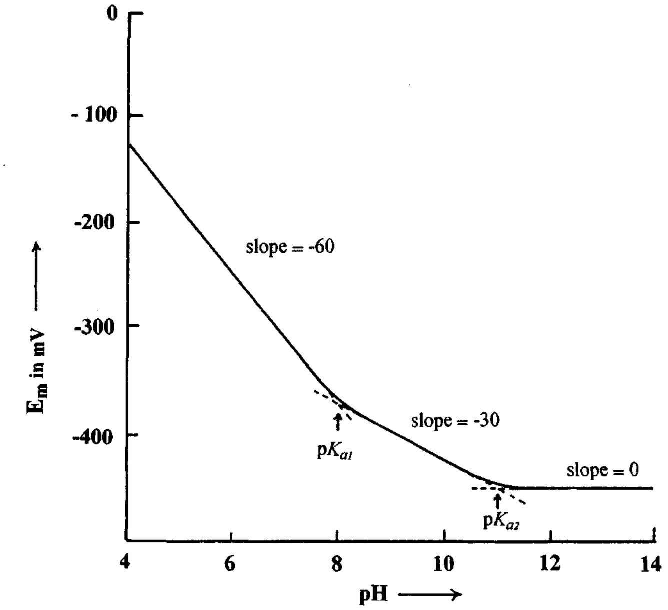

Figure 11-2 How pH Change Can Affect the Redox Potential of a Redox Couple. This is illustrated by a theoretical biprotic, weak acid (pK_a values of 8 and 11, and E_m at pH 7 of −300 mV), reduction of which, over the full pH range, is accomplished by the acceptance of two electrons per molecule. The slope of the relationship is most steep (−60 mV per pH unit increase) when two protons are simultaneously accepted. When only one proton is taken up per molecule along with the two electrons, then the curve is half as steep, and when no protons are implicated then the redox potential is independent of pH (in this instance >pH 12). *Source:* Adapted with permission from J.G. Morris, *A Biologist's Physical Chemistry,* 2nd ed., pp. 322–359, © 1974, Edward Arnold.

rium partial pressure of hydrogen). Unfortunately, because for many redox couples the relationship between E_h and pH was not as straightforward as for some others, *rH* values came to be inappropriately ascribed. Clark himself demanded[14] that the term *rH* should no longer be used because, "in brief, *rH* has become an unmitigated nuisance." However, should values of *rH* be encountered in some of the older literature, the corresponding values of E_h can be calculated provided the appropriate pH values are known,[34] for E_h at 30°C approximately equals $0.03(rH - 2\text{pH})$.

When reporting E_m (or $E°$) or E_h values that have been measured at pH 7 it is conventional to indicate this fact by assigning a superscript prime to the designation, eg, E'_m or $E°'$. Any other pH value (other than the standard pH = 0) is reported *verbatim,* eg, E_h at pH 6.4 = 234 mV. This enables comparative values of midpoint potentials of couples of biological interest (including redox dyes) to be listed as the more appropriate E'_m values (ie, relevant to systems at pH 7). Useful lists of these values have been published in several reviews.[14,28,34]

11.1.4 Redox Dyes

There exist a large number of organic chemicals liable to oxidation/reduction that are intensely colored in the oxidized or reduced state and either colorless or differently colored in the conjugate (opposite) state. For example, methylene blue (E'_m = +11 mV) is blue in its oxidized state but colorless in its reduced condition. Thus, if it were in solution to equilibrate with a redox system whose E'_h value was +50 mV it would confer upon it an intense blue color, for at this redox potential it would be 95% oxidized. However, in a system of E'_h −50 mV, methylene blue would be 99% in its reduced state and hence would impart no color to the system. Because redox dyes have been developed whose E'_m values cover the whole redox range of interest to biologists, the practice of using such substances as quick visual indicators of the prevailing redox potential of a solution is as usual as the similar use of pH indicator compounds.

The useful *transition range* of any redox indicator is that E_h span over which the fraction of the indicator that is present in its oxidized form changes from 90% to 10% of the whole (see Figure 11-1). However, here one encounters the first of several hazards in the indiscriminate use of such redox indicators because several of these compounds act simultaneously as pH indicators, whose acidic and basic forms also display distinctive colors.

To be effective, a redox indicator must rapidly and perfectly equilibrate with the redox potential of the test system; this also is not always achievable. Furthermore, the perfect redox indicator should be indifferent to the system whose redox potential it reports. Were it to be toxic to a biological component, or catalytic so that some reaction would occur in its presence that would not proceed at a significant rate in its absence, then it would be unacceptable. It should be noted too that redox indicators of the type described above undergo *reversible* redox transitions. This reversibility distinguishes them from other dyes whose reduction is almost irreversible, as in the case of the tetrazolium salts that are reduced to poorly soluble, intensely red or blue-colored formazans. Yet the near-irreversibility of the reduction of tetrazolium salts can also be advantageous. Thus Quastel and

Whetham,[66] when pioneering the use of methylene blue decolorization as a test of the ability of washed suspensions of bacteria to dehydrogenate various substrates, had to set up the reaction in evacuated Thunberg tubes to prevent aerobic reoxidation of the colorless leucomethylene blue. However, production of formazan from tetrazolium violet may be employed under aerobic conditions as a rapid test of the ability of a bacterium to utilize a range of substrates.[9] A rather more complicated situation exists in the case of resazurin which, over the E'_h range of +180 mV to +90 mV, is irreversibly reduced to the differently colored product resorufin. This, in turn, can serve as a reversible redox dye, being reducible ($E'_m = -51$ mV) to colorless dihydroresorufin. Thus, while resazurin (via its reduction to resorufin) has been employed under aerobic conditions as a relatively sensitive indicator of possible contamination of milk, it has also been widely used (via its further reduction with loss of all color) as an indicator of deoxygenation of anaerobic media.

11.1.5 Redox Buffering: Poising Effect

The redox potential of a redox couple (at a particular pH and temperature) is an *intensity term* whose magnitude (and sign) are only dependent on the nature of the couple, ie, its E_m value, and the ratio in which its oxidized and reduced forms are currently present. Put another way, how much of a redox couple is present will in no way affect its redox potential. Thus, a 70% oxidized redox couple will have the same E_h at a given temperature and pH whether its total concentration is 1 mM or 1 M.

On the other hand, the "resistance to change in redox potential" that is the basis of the redox buffering of a redox couple (also known as its poise or poising effect) will be determined by its total concentration as well as by the ratio in which its oxidized and reduced forms are present. The poising effect is thus a *capacity term* and the poising effect of a redox couple of a particular E_h will therefore be one thousand times greater if it is present at 1 M concentration than at 1 mM. The magnitude of its poising effect is manifested when the redox couple is titrated against a more potent oxidizing or reducing agent. Such a redox titration also makes it abundantly obvious that the poising effect of the redox couple is greatest when its oxidized and reduced components are present in equal amounts, ie, at its E_m value.

The relative redox buffering capacities, or poising effects, of all of the redox couples that are present in a system should (ideally) be taken into account when any attempt is made to interpret what is measured as the resultant redox potential of that system. Hewitt[28] illustrated this point by reference to the outcome of the addition of a redox dye to a biological system. At the prevailing pH and temperature, solutions of the dye would display the same E_h value irrespective of whether the dye was present in 0.001%, 1%, or 10% concentration. However, if a solution containing 100 g equiv. L^{-1} of the dye was mixed with a more reducing biological system containing only 1 g equiv. L^{-1} of the redox system responsible for its potential, then in Hewitt's words, "the dye could oxidize the whole of the biological system and still remain 99% oxidized, thus proving useless as an indicator of the condition of the system."

11.2 IN PRACTICE: REDOX POTENTIALS OF BIOLOGICAL SYSTEMS

11.2.1 Nonideal Behavior

The relationships described above would be displayed by ideal, reversible redox couples that interact with each other with no significant lag and that report their redox potentials via an inert electrode, again perfectly and immediately. The predictions that have been made also assume complete homogeneity of the aqueous systems involved, whose constituents are present in low concentrations that approximate to their activities.

Unfortunately, in practice many of these prerequisites are not met. Some redox couples are not easily reversible, some report potentials only sluggishly to measuring electrodes, and some interact only slowly with other couples except in the presence of specific oxidation-reduction catalysts. Also, in many foodstuffs such difficulties are compounded by their gross material and spatial heterogeneity, with phase differences and semisolid suspensions providing the conditions for the establishment of substantial gradients of redox potential over very small distances. When biological systems are involved, for example, in the case of microbial growth in a culture medium of any kind, it may appear that because very marked and rapid changes in redox potential can easily be measured, the redox buffering capacity of the system must be remarkably low. But it may be, as Hewitt[28] so graphically portrayed it, that "biological systems (can) behave, not as systems of fixed (redox) capacity or poising effect, but rather like a fountain-pen from which a small quantity of ink may be withdrawn for long periods at a slow rate. So that although the effective capacity of the biological system at any time may be very low, an almost inexhaustible process of reduction may proceed."

Attention to detail and technique can frequently help to overcome some of the difficulties encountered in obtaining reproducible and credible potential readings from a metallic measuring electrode. Jacob[34] emphasized the importance of careful preparation and cleaning of the electrode. When sluggish redox couples are involved, there are occasions when the addition to the system of a low (and hence not potential-distorting) concentration of another redox couple can cause this to serve as a mediator that rapidly reports to the electrode the potential generated by the test couple. Sometimes it can even be simpler than this. Thus, Rödel and Lücke[70] reported that to obtain stable and reproducible values when measuring E_h in sausage mixtures, it proved necessary to polish the surface of the platinum electrode prior to each measurement. Also according to Rödel and Lücke the hole punched for the insertion of the electrode "had to be wetted by a drop of 10 mM KCl to ensure good electrical contact between the product and the electrode. Without these precautions, 'phantom potentials' were frequently registered, or the time to reach stable reading was extended considerably."

By such means one can employ a platinum electrode, or its equivalent, to register an electrical potential at any site in an aqueous medium no matter how complex and heterogeneous this is. The difficulties arise in interpreting the causation and significance of the potential so measured. It is a temptation to attempt rigorously to apply the same reasoning that informs our understanding of the ideal systems outlined above. Unfortunately, this, more frequently than not, is a temptation that should be resisted. The chief danger is to be so beguiled by the reproducibility of measurement of a E_h value as to believe that this value must have some independent significance, that it serves as a determinant rather than as a reporter of the oxidized/reduced status of the system. If prone to this delusion, the best cure is to ask oneself what it is that is actually being measured. Will all of the redox couples potentially present in the complex substrate be so perfectly interactive that your instantaneous measurement will be of the redox status of the dominant (most oxidative couple) present in such concentration as to overwhelm all subsidiary couples? Or is it conceivable that the measured E_h value may take no account of the existence of some of the redox couples that are possibly present, because they are intrinsically sluggish (nonelectromotively active at the measuring electrode), or nonreversible, or for some other reason not accessed by the measuring device. The history of the measurement of redox potentials in bacterial cultures well illustrates these concerns.

11.2.2 Redox Potentials in Bacterial Cultures

Potter[65] was possibly the first to draw attention to the fact that a growing microbial culture generated a negative (ie, reducing) potential with respect to the uninoculated medium of initially identical composition. Thereafter, many investigators demonstrated the progressive fall in redox potential associated with growth and reproduction of bacteria in a variety of defined and nutritionally complex media.[2,11,13,23,28,32,34,35,44,59,64,68] This was noticeable even during the growth of aerobic bacteria in well-aerated media, though on the cessation of growth, the measured E_h of these batch cultures would generally rise again. This pattern of decrease in potential from an initial E_h value of somewhere around +350 mV to perhaps –50 mV with a subsequent rise during the stationary phase of batch culture contrasts with the behavior of cultures of facultative anaerobes.[28] In batch cultures of the latter, whereas, although initially the rate of decrease in E_h may be similar to that displayed by cultures of aerobic bacteria, after passing through a zone (around +270 to +200 mV) where the rate of decrease of E_h is slower and possibly indicative of some enhanced poising effect, thereafter the pace of E_h fall quickens again and the potential can attain a much lower final value (eg, –350 mV). Obligately anaerobic bacteria may not be able to initiate growth in oxygenated media (indeed, it is this that mostly distinguishes them from facultative anaerobes), but they may do so when the oxygen is removed and some reducing agent(s) is incorporated in the medium to decrease its initial E_h. Thus, addition of dithiothreitol can cause the E'_h of a medium to fall to quite low values (–250 to –300 mV). Once growth commences, however, then the E_h may rapidly diminish, in some instances (for example, when hydrogen is metabolically generated) achieving values more negative than –400 mV.

Such observations are very easily made and their reproducibility persuades one that they can be helpfully informative. In several instances a change in metabolic behavior in the course of bacterial culture growth is reliably signaled by a simultaneous change in the measured E_h. Monitoring E_h changes in microbial cultures, or alternatively controlling the E_h of a microbial culture in order to stabilize or amplify some desirable growth characteristic, has by now achieved respectability.[32,38,46,80]

Emde and Schink[18] achieved an increase in propionate formation by *Propionibacterium freudenreichii* by growing it in a 3-electrode poised-potential amperometric culture system, which employed either anthraquinone 2,6-disulfonate (poised E_h −224 mV) or cobalt sepulchrate (poised E_h −390 mV) as mediator. Yet in very few natural instances does the experimenter have any knowledge of precisely what is being measured by his recorded E_h value. Gillespie,[23] who in 1920 first applied the term *redox potential* to the electrode potentials measured in bacterial cultures, took comfort in the observation that "(their) biological significance may be capable of demonstration even if (their) chemical significance may not."

Hewitt[28] said that "definite electrode potentials are developed in cultures, but we are not fully aware what substances are responsible for these potentials in many cases, nor what reversible oxidation reduction systems are actually being measured." In her classic textbook on bacterial metabolism, Marjory Stephenson[78] picked her words very carefully when she wrote, "The fact that certain growth phenomena, eg, the germination of the spores of *Cl. tetanum* can occur only in conditions which give certain potential readings with the electrode, shows that the presence of substances associated with (not necessarily causing) these readings conditions the growth phenomena in question." There can be no doubt that what is being measured as the instantaneous platinum electrode potential in a bacterial culture is the resultant of the microorganism's metabolism of substrates provided by the growth medium and atmosphere, the outcome being a trend toward enhancement of the reducing intensity of the growth environment (sometimes amplified by its simultaneous acidification). An instantaneous E_h reading under these circumstances is at best a snapshot of a dynamic system; the crucial question is whether the electrode is actually recording that which is sensed by the microorganism. This becomes an especially important question when the primary determinant of the measured redox potential appears to be oxygen (aeration).

11.2.3 Oxygen and Redox Potentials in Bacterial Cultures

Being the most avid, pervasive, and generally available of biologically active oxidants, considerable attention has been paid to the fate of oxygen in bacterial cultures and to the influence that it has on the E_h values measurable in these cultures.[27,46,58,85] Were it to be reduced according to the following equation:

$$O_2 + 2H^+ + 4e^- \rightarrow 2OH^-$$

the E'_m value of the oxygen couple would be +810 mV at pH 7, and in an aqueous buffer at this pH, which was saturated with air the E_h due to oxygen would be expected to be +806 mV.[63] In practice, when using a suitably prepared platinum electrode, the E_h of a 0.666 M phosphate buffer pH 7 saturated with air at 1 atm was found to be +630 mV, while the E_h of a meat broth–peptone medium (pH 7) with a similar dissolved pO_2 of 0.2 atm, was only about +400 mV.[34] The above equation is therefore not an adequate representation of the fate of oxygen as oxidant in aqueous systems. Furthermore, besides its oxidative effect on the redox components of the medium, the possibility exists of direct interaction of oxygen with the measuring platinum electrode.[36] Experimental measurement of the relationship between the partial pressure of oxygen dissolved in nutrient media and the registered E_h value suggested that the E_h was proportional to the logarithm of the pO_2, the slope of the straight line relationship being 60 mV/log pO_2. On this basis, Jacob[34] calculated that the pO_2 in a culture of growing aerobic bacteria would be about 10^{-8} atm and in a growing culture of facultatively anaerobic bacteria about 10^{-12} atm. However, it is evident that the actual relation between pO_2 and E_h will depend on the chemical composition of the culture medium, which will change progressively due to the metabolic activities of the microorganisms whose growth it supports. Ishizaki et al.[32] reported that in bacterial fermentations a 10-fold change in pO_2 resulted in E_h changes of between 100 and 115 mV. Lund et al.[51] found that in an uninoculated peptone, yeast extract, meat extract medium containing thionine at 2 mg L^{-1}, there was a linear relation between pO_2 and E_h, such that, at pH 6.8 to 7.0, the medium responded to a 10-fold increase in pO_2 by a 138 mV rise in E_h.

Such extrapolations implicitly assume that in any bacterial culture, oxygen, when present, will be the dominant oxidant, it being ideally and instantaneously capable of accepting electrons available for donation by all couples of lesser E_h. This would be consonant with the view[85] that a major redox couple can swamp all other minor redox couples and therefore dictate the measured value of the culture redox potential. Were this the case, during an aerobic fermentation, the dissolved oxygen concentration should indeed be accurately mirrored in the measured value of the culture redox potential. Such an assumption would appear to be authenticated by the fact that in many microbial cultures it is possible to control the E_h value by adjusting the rate of aeration, or conversely, by controlling the E_h to regulate the rate at which air need be supplied. An interesting example of the practical utility of E_h control serving as proxy for dissolved oxygen control is provided by the way in which by maintaining at +40 mV the E_h of the surface aerated zone of an otherwise anaerobic reactor treating piggery waste water, aeration could be made intermittent and less costly while satisfying the objective of containment of foul odors.[4] Yet, it is not always the case that a simple equation can be made between dissolved oxygen and measured E_h for there are many examples of bacterial cultures being sustained at E_h values other than those that would be representative of the dissolved oxygen concentration in the medium. Kwong and Rao[45] showed that by fortifying the culture medium of *Corynebacterium glutamicum* with reducing agents such as dithiothreitol, it was possible to decrease the culture redox potential under aerobic conditions without affecting the high dissolved oxygen concentration. Thompson and Gerson[80] used a 50 V DC power supply and neutral red addition (at 0.25 μg ml^{-1}) to control electrochemically the redox potential of an aerated culture of *Escherichia coli* B/5 at +380 mV when, uncontrolled, the measured E_h would have been considerably higher. These, and other examples, counsel against (1) adopting a simplistic view of the relationship between dissolved oxygen concentration and measurable E_h in microbial cultures and other biological systems, and (2) assuming that all of the redox couples present in a biological system are perfectly reversible, highly electromotive, and capable of instantaneous interaction and equilibration.

11.2.4 Is It the Measurable Environmental E_h That Is Sensed by a Bacterium?

The point has been made that E_h has no existence independent of the couple whose redox intensity it reports. Also, in an ideal system of instantaneous equilibration of all available redox couples, it is that couple of greatest poise that will dictate the measured E_h of the system. Yet, even if this could be relied on, and it has been seen that such ideal behavior of mixtures of redox couples in biological systems cannot be assumed, the important question is whether it is this prevailing environmental E_h that is directly sensed and responded to by a bacterium. Some insight into the complexity of the problem can be gained by a consideration of the reaction of a bacterium such as *Escherichia coli* to oxidative stress caused by exposure to oxygen, and also of the regulatory mechanisms employed by this organism so to control gene expression as to exploit respiratory oxidants to best advantage.[33]

In its oxidative stress response, *Escherichia coli* responds differentially to hydrogen peroxide (via the OxyR regulon) and to superoxide anion (via the SoxRS regulon) rather than just to the high E_h that would simultaneously be sustained in its environment. Again, certain other bacteria respond to the oxidative stress provoked by aerobic exposure to benzylviologen and similar chemicals by accumulating 2-methylbutan-1,2,3,4-tetraol 2,4-cyclopyrophosphate, which in some undisclosed manner may serve as an antistressor,[60] although what these organisms perceive as the inducing stress is not known.

In the shift from aerobic to anaerobic respiratory and fermentative metabolism at least three gene regulatory systems are implicated in *E. coli*, viz. Fnr, NarL/Nar X, and ArcB/ArcA. The E'_m of nitrate/nitrite at pH 7 is +420 mV and, in the absence of oxygen, were nitrate to be available to *E. coli*, it would be the first of the alternative respiratory oxidants to be consumed. This primacy of nitrate usage is ensured by the *nar*L gene product acting in concert with nitrate and molybdate as a positive effector of transcription of the operons encoding the necessary nitrate reductase and formate dehydrogenase and repressing the expression of other anaerobic terminal reductases whose substrates have lower E'_m values, eg, fumarate/succinate E'_m +31 mV. Yet there is simultaneous overarching control from the FNR regulatory protein, which is functional only when oxygen is virtually absent from the environment. The presumption is that FNR (which is an Fe-S protein) is activated directly or indirectly by reduction but it is not known what is the electron donor in that reaction.[26]

The picture that emerges from these and other findings is that environment E_h can very possibly be sensed by bacteria via the altered redox status of some key component of their electron transport chains or (transcriptional) regulatory systems. For example, by displaying "redox taxis," *E. coli* (normal cytoplasmic midpoint redox potential < −250 mV[82]) demonstrates that it is able to sense the redox state of its surroundings and so swim to a favored position in a spatial redox gradient.[79] For this purpose a flavoprotein (Aer) serves as a redox sensor together with a serine chemoreceptor protein (Tsr), the pair also playing the same roles in the aerotaxis also displayed by the bacterium.[67] Other bacterial redox-regulatory switches that are responsive to oxidative stress are activated by a variety of mechanisms so that in some instances a specific oxidant can serve as the trigger of consequences that at first sight would appear to be more generally E_h determined. Thus OxyR senses peroxide-induced stress in *E. coli* via the oxidation of a cysteine thiol group to a sulfenic acid species, while SoxS that is responsive to superoxide radical-induced stress, uses a [2Fe-2S] cluster as the sensor. The FNR protein of *E. coli* employs cysteine-linked [4Fe-4S] cluster, while the FLP of *Lactobacillus casei* is a homodimeric protein wherein each subunit can on oxidation form an intramolecular disulfide bond.[24] Other redox responsive components of bacterial regulatory systems include the FixL hemoprotein of the two-component regulatory system for N_2-fixation in *Sinorhizobium meliloti,* and the NifL modulator of NifA-activated N_2-fixation in *Azotobacter vinelandii* that resembles Aer in using FAD as the redox sensor.[24] The situation is further complicated by the intimate relationship that exists between the redox status of the bacterial cell and its transmembrane proton motive force, which in turn reflects the "intracellular energy level" of the cell.[79]

There are instances when changes in environmental E_h affect bacterial metabolism even more indirectly. One example is provided by the particularly potent bacteriostatic action of nitrite on some food spoilage organisms. It remains a matter of some debate whether the additional enhancing effect of reagents, such as ascorbate or iron salts or thiols, is in this instance due to the formation of nitric oxide and iron-thio-nitrosyl complexes.[53,62] Pessimistically, one might reflect that any one organism could respond very differently to a particular E_h depending upon the chemical nature of the dominant poising couple.

11.2.5 Tentative Conclusions

Redox potentials can be easily and reliably measured in all manner of biological systems but, except in the most simple, it is rarely evident what (dominant) redox couple dictates this measured value. However, if one accepts the limitations of interpretation, then the measured E_h value and the rate and extent whereby it changes in response to events within the system can prove to be usefully informative. It is for this reason that E_h values measured in complex biological systems have variously been termed phenomenological values, empirical values, pragmatic values, even instrumentational values. *It cannot be stated too frequently that an* E_h *value reports on conditions, it does not of itself create them.*

11.3 REDOX POTENTIALS AND FOODSTUFFS

11.3.1 General Observations

In the context of food preservation and safety, the measurement of the redox potential of a foodstuff has the twin aims of (1) determining whether the substrate is capable of supporting growth of various classes of contaminant microbes, and (2) suggesting how the background redox potential might be so adjusted by the addition of a suitable oxidant or reductant as to make the substrate uncongenial to the likely microbial contaminants while not affecting its palatability and attractiveness as a foodstuff.[12] In the case of obligately aerobic microbes, the question might be asked whether the measured E_h value reflects the availability of dissolved oxygen so that it could signal when this achieves too low a concentration to sustain their growth. On the other hand, those obligate anaerobes that will not initiate rapid growth in an insufficiently reducing environment might be excluded if the E_h is poised at a sufficiently high value. In this context it should be noted that the redox buffering of certain foods is much higher than others due to their larger content of oxidants and reductants, so that microbial contamination that might cause a very marked change in the E_h of some less strongly redox buffered foodstuff might not significantly affect the E_h of another that is much more strongly poised. Such considerations will determine the nature and quantities of which preservative oxidants or reductants should be incorporated into the foodstuff and/or in what atmosphere this should be packaged in order to maximize its shelf life.

Anoxic packaging (under vacuum, or in carbon dioxide and/or nitrogen) will evidently exclude contaminant obligate aerophiles and will encourage the development of relatively low E_h values. To the same end, it has been suggested that copper(II) ascorbate could serve as an effective preservative in foods and beverages,[25] chiefly because of its ability rapidly to remove residual and headspace oxygen without generating damaging oxygen free radicals. A complication arises from the fact that some foods are of low E_h value even though they have been packaged in air. Thus, the measured redox potential of some delicatessen items was found to be as low as –198 mV to –23 mV, giving rise to concern that they might be more likely to pose a risk of botulism.[77] It has also been noted that the measured heat resistance of some facultatively anaerobic bacteria (including *E. coli* O157:H7, *Salmonella enteritidis,* and *Listeria monocytogenes*) is more than eight-fold greater when they were grown, heated, and (especially) recovered anaerobically rather than aerobically.[22] Thus, George et al.[22] concluded that "anaerobic enumeration should be used to give a realistic measure of the ability of the heat process to eliminate facultatively anaerobic pathogens from foods that are packed under vacuum or low oxygen modified atmospheres or that have a low redox potential despite being exposed to air."

In oral medicine, there is precedence for the antimicrobial use of various redox dyes. For example, topically applied methylene blue was employed in the treatment of periodontal disease. By raising the local E_h it inhibits the growth of causative, obligately anaerobic, bacteria.[21,84]

The pragmatic nature of any E_h measurement that is made in a heterogeneous system has already been emphasized. Unfortunately, this is not the only problem that is encountered by the food microbiologist who is also aware that many foods present a mosaic of possible habitat domains capable of supporting distinctive microbial communities. As time passes, these can change in population composition both due to progressive changes in the physicochemical characteristics of the substrate but also as their activity domains variously interact.[10] Shifting gradients of redox potential may also exist, most obviously paralleling gradient(s) of oxygen diffusion into the depth of a foodstuff. Despite these complications, it has generally been hoped that there will prove to be limiting E_h values or at least ranges of E_h, which, if not achieved, will ensure that growth of certain bacteria cannot occur, however suitable in other respects the substrate might be. Thus, in tests of strains of *Pseudomonas fluorescens* and *Salmonella* serotypes isolated from poultry, it was discovered that at pH 7, the limiting E_h for growth of the *Pseudomonas* was +80 mV.[42] In the same study, it was found that *Clostridium perfringens* affected growth of the pseudomonad in mixed culture at low values of E_h but not at an initial E_h of +200 mV, leading the authors to propose that, "with the increasing trend toward vacuum packaging of meats and poultry, the significance of oxidation-reduction potential on associative growth of aerobes and anaerobes warrants further study."

Plotz and Geloso[64] reported that any one of five clostridia rapidly lowered the E_h of anaerobic meat broth from an initial +80 mV to less than −200 mV at pH 7, although rapid growth occurred only when the E_h of the medium lay between −6 mV and −436 mV. Knaysi and Dutky[40] found that while growth of a butyric clostridium would not take place under aerobic conditions at +300 mV, it would do so when the dissolved oxygen tension was low and the medium was poised at +335 mV by the addition of ferricyanide. On the other hand, Kliger and Guggenheim[39] found that *Clostridium welchii* (ie, *C. perfringens*) would grow in a medium at 95% of the air-equilibrated oxygen tension provided that sufficient ascorbate was present to poise the medium at −125 mV. The larger the inoculum of vegetative cells that was used, the higher (up to about −90 mV) was the initial E_h that was compatible with growth of several pathogenic clostridia.[68] Fildes[20] had earlier pointed out the likelihood that the E_h in the vicinity of a dense, nondispersed inoculum of clostridial cells fell much more rapidly that when the same inoculum was more evenly distributed throughout the medium. Morris and O'Brien[58] reviewed these and other reports: (1) of the lowest values of E_h developed in growing clostridial cultures, (2) of the upper limits of E_h at which such growth could be initiated, and (3) of the particular situation in which dissolved oxygen was the determinant of the measured E_h. They concluded that in the case of any *Clostridium*, the magnitude of the limiting culture E_h above which the vegetative organism will not grow (variously reported as being between +30 mV and +250 mV), will not be invariant but will be determined by several factors including the composition of the medium, the inoculum size, whether or not the E_h is artificially maintained and, if so, by what agency. Quite early on, it was recognized that media components that were not themselves redox active, and a variety of other stress-inducing factors (including nutrient deprivation, suboptimal pH values) could affect the outcome. Thus, Mead[54] found that with *Clostridium perfringens* growing in a complex medium in the presence of 0.5% NaCl, the upper limit of E_h compatible with growth was +194 mV, but as the concentration of NaCl was further increased the limiting E_h decreased until at 5% NaCl its value was +66 mV.

In the case of clostridia, and especially *Clostridium botulinum* (see below), interest has centered not only on the range of E_h values over which the growth of vegetative cells may be initiated, but also on the oxidation-reduction potential limits that dictate whether or not their endospores can germinate. In general, the germination of spores of *Clostridium* species is less oxygen sensitive than is the growth of the emergent vegetative bacteria. However, in anoxic conditions a marked fall in culture E_h can accompany the germination of a large spore inoculum, thereby providing the conditions suitable for the multiplication of the outgrowing vegetative cells. Thus, following inoculation of a culture medium with 3.4×10^7 *C. butyricum* spores ml^{-1}, the culture E_h fell from +200 mV to less than –200 mV within 1 hour,[17] a fall that was seemingly associated with the fermentative production of hydrogen gas. Inoculum size may also influence the value of the determined growth-limiting E_h because the larger the number of spores/organisms employed, the greater the likelihood that among them there will be variant individual(s) capable of better tolerating adverse redox conditions.[50]

Although the majority of such studies have been performed with laboratory culture media, there are circumstances when the findings are mirrored in observations made with foods.

11.3.2 Milk and Dairy Products

The dairy industry has notably employed various redox dyes in rapid qualitative tests of milk purity. Thus, because raw milk has an E'_h of about +200 mV under aerobic conditions, added methylene blue (E'_m = +11 mV) will not be reduced and hence decolorized unless the milk is significantly contaminated with unwelcome bacteria. Resazurin in its reduction to resorufin (see Section 11.1.4) is a rather more sensitive indicator of the presence in milk of mastitic pus and tissue cells. Though hopes have been expressed that the rates of reduction of some of these redox indicators might prove to be proportional to the load of microbial contaminants in the dairy product, this would not appear to be the case. Furthermore, the rates of reduction of various redox dyes by foodborne bacteria vary greatly between different bacterium/dye combinations, so that with any one dye, there is considerable variation with each organism and between different organisms.[47] Care must therefore be taken in interpreting the findings made in such dye reduction assessments of microbial contamination.[43]

Somewhat surprisingly, sterilized milk is a poorly poised medium. The redox potential of milk sterilized by heating at 115.5°C for 15 minutes in evacuated bottles was –290 mV, but milk similarly heated in open bottles in air had an E_h of –30 to +10 mV. Milk heated in such a way as to conserve/produce reducing components that are evidently sensitive to aerobic oxidation did not support as rapid growth of *Bacillus cereus* 201 and *B. brevis* 58 from small spore inocula as did milk heated in open bottles.[29] The method used for sterilization and the oxygen permeability of the final packaging may both affect the redox potential of the product. For example, samples of UHT single cream in Tetrapak© containers prepared aerobically by two different processes displayed mean E'_h values of +286 mV and +222 mV, respectively (Dr. B.M. Lund, personal communication). To achieve this degree of accuracy and reproducibility of redox potential determination in an aerobic system, it was necessary before each measurement to clean the measuring electrode and restandardize it in aerated phosphate buffer.[51] Even so, the prepared and oxygen-responsive electrode then had to be immersed in the cream under a stream of oxygen-free nitrogen for between three and five hours before stable readings were registered.

In making measurements of redox potential changes in ripening cheddar cheese Davies et al.[16] found that oxidative taints and oiliness did not appear when the E_h at pH 6.5 was less than +300 mV. On the other hand, anaerobic faults such as *rusty spot* did not appear when the E_h at pH 5 was above –100 mV. Gassy fermentations were preventable by adding oxidants. In this respect, nitrate was particularly effective, though this was more likely due to nitrite and its products being particularly inhibitory to the growth of organisms such as *Clostridium tyrobutyricum*. The electrode potential measured in the interior of a ripening cheddar cheese followed a predictable course indicative of the initial establishment of an almost pure culture of *Streptococcus lactis* followed in later stages by a lactobacillus.[28] The development and variations in gradient(s) of E_h within cheeses could also be informative. In Brie cheese, oxygen gradients were steep in the uppermost 2 mm of the cheese and below this level the cheese was essentially anaerobic. A pH gradient deriving from lactic acid production extended from acid (pH 5.5) in the center to more neutral pH values toward the surface. Each of these contrary gradients was established by microbial activity, and just beneath the fungal rind, the pH and oxygen tension were mutually appropriate for the growth of *Listeria monocytogenes*.[10]

11.3.3 Meats and Meat Products

Barnes and Ingram[5] reported that the redox potential of horse muscle fell after death from +250 mV to –130 mV. At the onset of rigor it was 0 mV to –50 mV, and below –36 mV it supported rapid multiplication of *Clostridium perfringens*. This fall in E_h of carcass meat is due to the continued activity of indigenous enzymes during the cooling period. Simultaneously, the oxygen reserves in the depth of the muscle become depleted, and the pH decreases. Thus, for a period, the E_h remains relatively high as the pH becomes more acidic, allowing time for the carcass to cool to a safe temperature before conditions become appropriate for the growth of obligately anaerobic bacteria. Thereafter, much depends on the manner in which the meat is processed and packaged. Methods for the measurement of E_h in meat products have been published[48,71] and there is ongoing interest in the preservative role of nitrite[31] (see also Chapter 9).

Madden and Bolton[52] measured E_h as well as pH and numbers of aerobic, microaerophilic, and anaerobic microorganisms in fresh beef and a chicken liver paté, which had been vacuum packed prior to refrigerated storage. The beef showed a rapid fall in surface E_h, which then stabilized until the anaerobic microflora (largely lactic acid bacteria) was established. Analyses undertaken on the exudate from commercially produced vacuum packs of beef primal cuts showed significant correlations between the numbers of both anaerobic and microaerophilic organisms and negative E_h values. They concluded that E_h is a significant parameter affecting, and affected by, the growth of anaerobes, and that its measurement may serve as an indicator of their number. In minced fresh meats that are loosely packed under an air-permeable film, the surface E_h will remain relatively high and the major bacterial contaminants are likely to be pseudomonads and *Brochothrix thermosphacta* plus lactic acid bacteria. Antioxidants that rely on bisulfite and sulfite for activity delay microbial spoilage of certain meat products, and other antioxidants, such as butylated hydroxyanisole and butylated hydroxytoluene used to counter rancidity, are now known to inhibit the growth of Gram-positive bacteria.[72] Wirth and Leistner[86] suggested that an initial E_h between –20 mV and –150 mV is optimal for canned meats, with additives such as nitrite and ascorbate contributing to the poising effect. The shelf life of pasteurized meat products that are packaged in hermetically sealed containers is likely to be compromised by the growth from viable spores of *Bacillus* as well as *Clostridium* species, with *B. subtilis, B. pumilus,* and *B. licheniformis* predominating.[7] However, from studies undertaken with Bologna-type sausage mixtures infected with these *Bacillus* species, Rödel and Lücke[70] concluded that the microbiological stability of pasteurized meat products cannot be predicted from measured redox potentials alone.

11.3.4 Redox Potential, Oxygen Tension, and the Probability of Growth of *Clostridium botulinum*

For obvious reasons, much attention has been focused on determining those properties of foods (fish, meats, milk, canned products) that predispose them to be unsuitable media for spore germination, and subsequent vegetative cell multiplication, of *C. botulinum* types A and E. One question has been whether a reliable ceiling value can be placed on the oxidation-reduction potential span that is compatible with growth of this pathogen from spore inocula in a given medium.[1,50,56,75,76] The evident inability of *C. botulinum* to grow in the presence of even modestly high concentrations of oxygen similarly caused assessments to be made of the limiting oxygen concentration for vegetative cell growth. Early estimates placed this limit at about 4% to 9% of normal atmospheric oxygen tension,[15,55] although germination of spores of *C. botulinum* type E can, under certain circumstances, occur in aerated media.[1]

Milk sterilized by autoclaving at 121°C for 18 minutes registered an E_h value of +234 mV which, due to autoreduction, decreased to +189 mV in six days of standing. When the newly sterilized milk was inoculated with 2×10^3 to 5×10^3 spores ml^{-1} of *C. botulinum* type 62A, there was a lag time of seven days before growth began.[37] More prolonged (30 minutes) heating of the milk at 121°C yielded a product with an initial E_h of +192 mV, which fell during six days standing to +129 mV. In this medium, the lag time for growth from the same-sized inoculum of *C. botulinum* type 62A was only five days. In both cases, inoculation of the milk samples three or five days after sterilization led to a shorter lag phase than when the medium was inoculated two hours after autoclaving. This led Kaufmann and Marshall[37] to conclude that the autoreductive property of sterilized milk played a major role in development of conditions suitable for growth therein of *C. botulinum* type 62A.

These and other early studies suggested that whether or not a particular culture medium was capable of supporting growth of *C. botulinum* (all other factors being propitious) might be as much dependent on the nature of its major oxidant as on its measurable E_h value. Thus, when a *C. botulinum* type E was injected (at 100 spores g^{-1}) into the muscle of freshly smoked herring, which was vacuum packed and then stored at 15°C, botulinum toxin was formed within three days despite the fact that the E_h of the muscle remained almost constant in the range +200 to +250 mV.[30] This despite the fact that in normal culture media the highest possible E_h at which growth of *C. botulinum* type E was initiated was considered to be +200 mV at pH 7. Indeed, Ando and Iida[1] had previously reported that although large inocula (10^8 spores ml^{-1}) in an aerated culture medium of E_h +293 mV germinated, they showed no further post-germinative development. However, in the herring muscle the major oxidant would be not oxygen but trimethylamine oxide which can actually be utilized by *C. botulinum* type E as an electron acceptor.[49]

The presence of a preservative, for example, NaCl,[19,50] can significantly affect the E_h range within which growth of *Clostridium botulinum* may be initiated. Segner et al.[73] found that with an inoculum of 2×10^5 viable spores ml^{-1}, 5% w/v NaCl inhibited the growth of three strains of *C. botulinum* type E for one year during incubation at 16°, 21°, or 30 °C. When trypticase soy broth containing 4% NaCl was inoculated with 3×10^6 spores ml^{-1} of *C. botulinum* type E, if the medium was adjusted to E'_h −190 mV, growth was apparent after 48 hours at 30°C, but if the E'_h was −80 mV, no growth occurred during 200 hours incubation at this temperature.[74] Lund and Wyatt[50] found that the probability of growth in five days from a small spore inoculum of *C. botulinum* type E strain Beluga introduced into a culture medium of pH 6.8–7.0 containing 0.1% NaCl, was not significantly different at E_h +60 mV (with introduced air) than at −400 mV (anaerobic). Increasing the E_h above +60 mV, however, decreased the probability of growth, so that between +122 mV and +164 mV, this was 10^5-fold less than that evidenced at −400 mV. Raising the NaCl concentration to 3.25% and 4% in the anaerobic medium of E_h −400 mV decreased the probability of initiation of growth by factors of 10^2 and 10^4, respectively.

Riemann[69] suggested that the success of any preservation method with respect to infection of food by *C. botulinum* could be gauged from its effect on the probability that one botulinum spore would grow out and so produce toxin. Lund[49] and colleagues adopted this principle in computing the probability (*P*) for initiation of growth from a single spore of *C. botulinum* when small spore inocula were employed to infect various culture media. Recognizing that it is not possible to make simple correlations between dissolved oxygen concentrations and E_h values in dif-

Table 11-1 The Effect of Partial Pressure of Oxygen on the Redox Potential of the Medium and on the Probability (*P*) for Initiation of Growth from a Single Spore of *Clostridium botulinum* type E

pO_2 (atm × 10^{-2})	E_h (mV)	*Log* P *for Growth in Days*

ferent media, they further recommended that both parameters should routinely be measured and recorded. Table 11-1 reproduces their findings concerning the effect of partial pressure of oxygen on the redox potential of the culture medium and on the probability of initiation of growth from a single spore of *C. botulinum* type E. These and similar observations made by other workers explain why oxygen should be expelled, and good reducing conditions established, before an attempt is made to quantify the effects of any other possible preservative on the growth of *C. botulinum* (an E'_h of -200 mV to -300 mV, or lower, was recommended.[49]

11.4 CONCLUDING REMARKS

Redox potentials in foods are relatively easily measured but the values so obtained are difficult to interpret wisely. They are the result of contending oxidative and reductive tendencies attributable to components that are present in differing concentrations (and hence poising effect) and which may not be in perfect equilibrium nor equally electromotive at the measuring electrode. Yet the alternative use of redox dyes to indicate redox potentials is fraught with so many difficulties that, for quantitative purposes, use of electrode-based measuring instruments is obligatory. This imposes the further requirements (1) that the measuring electrode be so prepared and calibrated that it gives stable and reproducible readings, and (2) that a foodstuff is tested in a manner that does not cause any change in the potential that is to be measured (eg, a food should be tested in the atmosphere in which it is packaged with precautions being taken to avoid ingress of air when this has previously been excluded).

Despite these concerns, measured E_h values, and time-dependent changes therein, can prove helpful as one of several indicators of the susceptibility of a food to microbial infection and of the course of consequential microbial activities, providing information, which, in turn, can inform choice of an appropriate combination of preservative measures. At the same time, it would be unwise to use redox potential information in isolation to predict food safety, or to rely exclusively on control of redox potential as the means of preventing growth of specific microorganisms.

12.1 INTRODUCTION: HISTORICAL PERSPECTIVE

Use of biocontrol (biological preservation) in foods or the use of microorganisms and their products in the preservation of foods predates recorded history. This earliest aspect of food biotechnology evolved with the global development of fermented foods and beverages. Along with salted and dried foods, fermented foods represent the first processed foods. Through serendipity and realization passed down through generations, people lacking scientific understanding discerned the advantages of the production and consumption of cultured foods. Societies matured with the discoveries that these new products provided a source of nourishment more resistant to spoilage and less likely to cause food poisoning while increasing the seasonal availability of foods and offering new taste sensations. Even with the advent of new and improved food technologies involving production, harvesting, processing, packaging, and storage that reduce the importance of fermentation for food safety and shelf life, fermented foods and beverages continue to represent a major segment of the diet for people around the world.

The means by which fermented foods and beverages resist deterioration from spoilage microorganisms (and to some extent degradative enzymes) include the release of antimicrobial metabolites (eg, organic acids, bacteriocins, alcohols, fatty acids, enzymes) and alteration of the conditions in the food (eg, lowering of redox potential or water activity and competition or removal of nutrients and growth factors). In most cases, conditions are provided in the foodstuff to select for the fermenting microbiota to bring about desired changes. For example, the addition of salt and the maintenance of anaerobic conditions, as is the case for many fermented meats and vegetables, allows for the selection of various types of lactic acid bacteria that are originally present in the foods in relatively low numbers. With fermentable sugars present, and given the inherent ability of lactic acid bacteria to thrive in conditions of high salt concentration and anaerobiosis, the lactic acid bacteria flourish and the food is stabilized by a combination of acids produced by the lactic acid bacteria in accompaniment with the salt and other preservative compounds and conditions that pertain.

More recently, it has been established that some of the compounds produced by fermenting cultures can be extracted and purified for use as additives to preserve foods. Presently, consumer demand grows for foods minimally processed or reformulated to remove fat and salt while lowering calorie levels. In addition, there is a perceived advantage to "natural" foods or foods devoid of preservatives and chemical additives. One approach to deal with this trend while maintaining product safety, shelf life, and acceptance is to use "natural" by-products, extracts, or cultures of food-grade or GRAS (generally regarded as safe) microorganisms that have a long history of use and safety in fermented foods and beverages. New applications of such preservative agents should not significantly change the sensory characteristics of the food. Nisin, the bacteriocin produced by some strains of the cheese starter bacterium *Lactococcus lactis* subspecies *lactis*, has been the prime example of a microbial by-product that can be used successfully as a food preservative. This chapter will examine the characterization and use of bacteriocins for purposes of food preservation.

12.2 THE PRESERVATION OF FOODS INVOLVING TRADITIONAL METHODS OF FERMENTATION

Fermented foods and beverages are covered in several chapters in this book. This chapter will summarize the preservation mechanisms functioning in fermented products that reduce or prevent their spoilage and enhance the safety of the product, and overview the natural compounds that are produced by microorganisms and are active preservative agents.

12.2.1 *Saccharomyces cerevisiae* and the Killer Factor

Arguably, from a commercial standpoint the most important microorganisms in the production of fermented foods and beverages in the world are the fermentative yeasts, based on world consumption of alcoholic beverages and leavened breads. The most widely used of this group of microorganisms is *Saccharomyces cerevisiae*. This commercial importance has resulted in a wealth of scientific study on strains of *S. cerevisiae* both in the areas of basic yeast biology and applied starter culture technology.

From a food preservation standpoint, *S. cerevisiae* and other ethanologenic yeasts establish an environment nonconducive to growth of other microorganisms by excretion of large quantities of ethanol and carbon dioxide. Also, various acids are released as a result of the metabolism of sugars and significantly lower the pH. Ethanol has long been used as a disinfectant and represents one of the significant preservative components of alcoholic beverages.[208] The evolution of carbon dioxide from metabolizing strains of yeast also acts as an antimicrobial agent.[43,73] Conditions of anaerobiosis are generated in foods and beverages fermented by yeasts by the production of carbon dioxide along with the utilization of oxygen by the metabolizing yeast. Fermentative sugars, vitamins, minerals, and other nutrients are quickly utilized by metabolizing yeasts depriving these nutrients from competitive microbiota.

The levels of ethanol, carbon dioxide, acids, and other by-products from the metabolism and growth of yeast change the sensory quality of the product. As with nisin, an antibiotic substance from yeast that could act as a food additive for purposes of preservation would prove valuable if such a compound was safe and effective at low concentrations while imparting no significant changes in the aroma, taste, texture, and appearance of the product. Killer yeasts appear to have potential for the production of such preservative compounds.

Killer yeasts were first documented in 1963.[22] They are able to inhibit the growth of other yeasts by the production of toxins. Analogies can be made with bacteriocin production in bacteria.[174] Killer yeasts are resistant to the toxins they produce, and these toxins have a somewhat narrow target spectrum, effective only against specific types of other yeast. Molds, bacteria, and viruses are not affected. Killer toxins of yeast act to destabilize the integrity of the cellular membrane by forming and interfering with amino acid uptake[169] ion channels.[160,230] These extracellular toxins are proteins or glycoproteins with a molecular weight of approximately 32,000.[25,33] The binding of the killer toxin to the cell is by a specific receptor.[35] Just as contaminating nisin-positive lactococci slow or eliminate the activities of industrial cheese starter lactococci, so have contaminating killer yeast proved lethal to commercial ale and lager strains of yeasts.[163]

The killer and resistance factors in yeast are mediated by a double-stranded RNA (dsRNA) that resembles an intracellular virus.[208] Yeasts lacking this dsRNA are usually eliminated by the killer factor. Two forms of the dsRNA have been identified: MdsRNA and LdsRNA.[261] MdsRNA is found only in killer strains of *Saccharomyces* and encodes for the toxin and the immunity factor. Cells of killer strains harbor about 12 copies of the MdsRNA. LdsRNA is more common and has been found in both brewing and killer strains of yeast. Apparently its function is to encode for the capsid protein of the virus-like particle that surrounds the dsRNA. During cell replication, these particles are extracellularly maintained with some regulation from a chromosomal gene for expression of the killer phenotype.

The advantages of genetically modifying brewing strains with killer factors are that such cultures would be immune to the effects of contaminating wild killer yeast, and wild nonkiller yeast would be deterred from contaminating the fermentation by the killer brewing strain. This situation should theoretically help reduce the occurrence of faulty fermentations, although quality control/good manufacturing practices would represent the primary means of ensuring successful fermentations.

Killer toxins have been designated K1, K2, etc, with at least 10 types described, although only one toxin is produced for each strain of killer yeast.[208] Killer strains of *S. cerevisiae* are ineffective against *Candida* spp., *Pichia* spp., *Debaromyces* spp., *Kloeckera apiculata*, and several other yeasts. Commercial uses of this antagonistic mechanism have been inconsistent due in part to this somewhat limited spectrum of antagonistic action.

K1 toxin is the most highly characterized killer toxin with a molecular weight of 20,000.[26] It has α and ß subunits of 103 and 83 amino acids, respectively, linked by disulfide bonds. It appears the α subunit is responsible for the ion channel formation while the ß subunit binds to the cell wall receptor. A concentration of 2.3 ng ml^{-1} of K1 will kill approximately 2.0×10^7 cells of yeast ml^{-1}. The killing of the cells is an energy-dependent process that takes about 1 to 3 hours.[34] Macromolecular synthesis is followed by loss of K^+ ions and ATP with loss of amino acid uptake and cessation of proton pumping. As seen with many bacteriocins, cell lysis is not caused by the killer toxins.

Killer yeasts are generally only effective in the pH range of 4.0 to 5.4 and are ineffective at temperatures less than 30°C.[125] Such parameters limit the use of killer yeast in wine-making, although genetic modification could broaden the range of killer yeast effectiveness in these fermentations.

Yeasts are not necessarily limited to killer toxins as possible biopreservative agents. Suzzi et al.[240] examined 586 natural wine yeasts of different genera for antagonism to fungal pathogens isolated from fruits and soil. Fungal species representing *Aspergillus*, *Alternaria*, *Botrytis*, *Cladosporium*, *Fusarium*, and *Penicillium* among others were included. Two strains of *S. cerevisiae* and one of *Zygosaccharomyces* exhibited a broad spectrum of antagonistic activity against 10 fungal pathogens. McLaughlin et al.[167] found that *Candida* spp. displayed antagonism to a range of different fungal pathogens. Ben-Arie et al.[19] demonstrated that *Hanseniaspora uvarum* was effective against species of *Rhizopus* and *Botrytis*. Other researchers have found similarly effective growth inhibition of yeasts against molds.[166,210,262] The use of yeasts as effective biocontrol agents in fruits and vegetables has been suggested and continues to receive considerable attention[263,264]; however, there is no evidence of successful commercial adaptation.

12.2.2 Acidulating Bacteria

Organic Acids

As their name implies, the important unifying trait of the lactic acid bacteria is the production of organic acids (specifically lactate) from fermentable sugars. The lactic acid bacteria traditionally used in the production of acidulated, fermented foods or as probiotic additives are identified as GRAS organisms. However, there is concern that lactic acid bacteria occasionally can act as opportunistic or secondary pathogens and, in fact, the frequency of reports associating lactic acid bacteria with human clinical infection has been increasing.[1,100] It is well-known that some types of acidulating or lactic acid bacteria reside in the mouth and cause dental caries (eg, *Streptococcus mutans*, *Bifidobacterium dentium*), but these types are not used as starter cultures nor are they active in food fermentations. Of the food-associated lactic acid bacteria, the enterococci are probably the major focus of safety concern due to their intrinsic resistance to a wide range of antibiotics, presence in the human gut, and capability to transfer antibiotic resistance to pathogens.[1] In addition, enterococci have been isolated from human infections. Also of concern are the reports about members of the genus *Leuconostoc* responsible for generalized infections in adults, and some species of *Lactobacillus* associated with endocarditis and localized infections.[1] Therefore, even though food-related lactic acid bacteria have a well established, extensive record of safety and benefit, an awareness of their possible human pathogenicity is prudent. Certainly an *in vivo* assessment of the disease potential of lactic acid bacteria using improved modern methods of isolation and identification would be most valuable.

The means by which lactic acid bacteria deter undesirable microorganisms include the primary metabolites produced by carbohydrate catabolism (organic acids, carbon dioxide, alcohols, aldehydes, and ketones), hydrogen peroxide, diacetyl, and bacteriocins. Other types of antagonistic compounds (such as reuterin) have been documented as well, indicative of the rather complex antagonistic systems created by metabolizing lactic acid bacteria.[64]

Foremost in contributing to the preservative effect of lactic acid bacteria and other food-related fermenting bacteria, such as the propionibacteria and bifidobacteria, is the production of organic acids such as lactic, acetic, and formic acids. The drop in pH combined with the presence of these weak organic acids readily creates an environment hostile to many types of spoilage and pathogenic bacteria, as well as some fungi. The undissociated forms of the acids can pass through the cytoplasmic membrane and then dissociate intracellularly (see Chapter 8).[29] Acetate (pK_a at 25°C = 4.75) is a more effective inhibitive agent than lactate (pK_a at 25°C = 3.86) to some extent because of its higher dissociation constant.[70,112]

In lactic acid bacteria, ATP is synthesized by an extremely efficient carbohydrate fermentation coupled to substrate-level phosphorylation.[10] Under optimal conditions of growth, the homofermentative lactic acid bacteria (lactococci, pediococci, streptococci, and some lactobacilli) produce lactic acid almost exclusively from utilization of fermentable carbohydrates using the Embden-Meyerhof-Parnas pathway (glycolysis). Leuconostocs and heterofermentative lactobacilli use the hexose monophosphate shunt employing phosphoketolase. This pathway results in carbon dioxide and ethanol being produced in addition to lactic acid. Under nonoptimal growth conditions or by the utilization of certain substrates, homofermentative lactic acid bacteria employ the hexose monophosphate shunt that leads to end-products other than lactic acid.

Given the end-products produced during fermentation, bifidobacteria and propionibacteria could also be technically described as heterofermentative lactic acid bacteria; however, the pathways and end-products of these two microbial groups deviate from the hexose monophosphate shunt used by leuconostocs and heterofermentative lactobacilli. Bifidobacteria and propionibacteria are not closely related to the conventional lactic acid bacteria, but belong to the Actinomycetes. In *Bifidobacterium*, hexoses are degraded exclusively by the fructose-6-phosphate pathway that features fructose-6-phosphate phosphoketolase.[63,220] The acids from this pathway vary among the bifidobacteria. These primary metabolites are acetic and lactic acids with formic acid sometimes produced.[12] During the making of Swiss cheese, *Propionibacterium* convert lactate produced by lactic acid bacteria into carbon dioxide, propionate, acetate, and carbon dioxide.[106,149] The antimicrobial effectiveness of propionic and acetic acids are enhanced by the low pH found in fermented foods.[15]

Hydrogen Peroxide

Hydrogen peroxide is a highly reactive compound; in high concentrations it is quite toxic to biological systems. In aseptic processing, it is used to sterilize packaging containers. Lactobacilli, lactococci, leuconostocs, and pediococci are capable of producing hydrogen peroxide when grown in the presence of oxygen through electron transport by different mechanisms involving flavin enzymes.[49,139] Because lactic acid bacteria are catalase-negative, hydrogen peroxide can accumulate to high, autoinhibitory levels in the growth medium,[9] although the induction of stress proteins allows lactic acid bacteria to tolerate higher concentrations than other types of bacteria.[47] Bacteria such as pseudomonads and *Staphylococcus aureus* are up to 10 times more sensitive to hydrogen peroxide than lactic acid bacteria.[112] For example, evidence has been provided for the contribution of hydrogen peroxide in the inhibition of pseudomonads by *Lactobacillus plantarum*,[197] *L. delbrueckii* subspecies *bulgaricus*,[84] *L. delbrueckii* subspecies *lactis*,[159] *L. acidophilus*,[44] and lactococci.[136] Because lactic acid bacteria can produce a complex array of antimicrobial substances and create conditions that are unsatisfactory for spoilage and for the growth of pathogenic organisms, it is difficult to segregate the effectiveness of one factor from other factors, especially because the sensitivities of target microorganisms is often blurred by the combination and synergy of individual antagonistic factors.[64,85,200]

The Lactoperoxidase System

In raw milk, hydrogen peroxide also functions in the lactoperoxidase system.[13,209] Lactic acid bacteria contribute to the functioning of this system by generating hydrogen peroxide; starter cultures have been known to enhance the lactoperoxidase system. Notably effective against pseudomonads and other Gram-negative psychrotrophs, lactoperoxidase in raw milk catalyzes the oxidation of thiocyanate by hydrogen peroxide to form hypothiocyanite ions, higher oxyacids, and labile oxidation products.[81,196] Bovine milk naturally contains lactoperoxidase, thiocyanate, and hydrogen peroxide, but to make an effective preservation system, thiocyanate and hydrogen peroxide are often added (12 and 8 ppm, respectively). This system works optimally at 30°C and can extend the shelf life of raw milk from two days to five days. This makes the lactoperoxidase system a potentially important means of preserving milk in those parts of the world where refrigeration and use of pasteurization are limited.

Other Low Molecular Weight Metabolites

The fragrance and flavor of butter is delivered primarily by the compound diacetyl (2,3-butanedione).

Diacetyl, derived from the catabolism of citrate, is excreted by lactococci, pediococci, and leuconostocs. In products such as cream cheese and buttermilk, diacetyl is highly desirable, while in beer, even trace amounts are avoided. Diacetyl has been shown to have an antagonistic effect against a range of microorganisms including yeasts and molds as well as bacteria,[99,130,179,194] but its intense aroma and volatility severely limit its use in foods where the presence of diacetyl at effective, preservative levels (200 to 400 μg ml^{-1}) would be necessary.[53]

Reuterin is produced by *Lactobacillus reuteri* from the anaerobic catabolism of glycerol and glyceraldehyde.[11,39,242] This compound, not a bacteriocin, is an equilibrium mixture of monomeric, hydrated monomeric, and cyclic dimeric forms of ß-hydroxypropionaldehyde. Reuterin is strongly antagonistic against a wide range of Gram-negative and Gram-positive bacteria, yeasts, molds, and protozoa, probably because of the inhibition of ribonucleotide reductase.[243] The addition of reuterin to refrigerated ground beef effectively inhibits *Escherichia coli* and other microorganisms resulting in a shelf life extension compared with controls (Figure 12-1). When *L. reuteri* and glycerol are topically applied to herring, surface spoilage bacteria and accumulation of total volatile basic nitrogen are reduced during refrigerated storage under controlled atmospheres.[152] It appears that reuterin or reuterin-producing *L. reuteri* have the potential for use as biopreservative agents for refrigerated meats and seafood.

Microgard®

Microgard® is a commercial food additive that is a growth extract from *Propionibacterium freudenreichii* subspecies *shermanii.* Skim milk is fermented with the propionibacteria and then pasteurized to inactivate the culture.[254] The antagonistic effect of Microgard® is due to the metabolic by-products from the culture that includes acids, bacteriocins, and diacetyl.[7] It is marketed as a food preservative for use in such products as cottage cheese and fruit-flavored yogurt.[217] Microgard® has broad-spectrum activity against Gram-negative bacteria, yeasts, and some molds. Salih et al.[217] found Microgard® effective against Gram-negative psychrotrophic bacteria (Figure 12-2); the shelf life of cottage cheese was extended 6 to 9 days. Although the active components of the mixture have not been completely characterized, Al-Zoreky et al.[7] have identified a bacteriocin of 700 daltons that appears to generate considerable antimicrobial effect. Apparently, a newer version of Microgard®, which has nisin and other bacteriocins added, will soon be on the market. Given the relative success of Microgard® in the marketplace, other growth extracts using GRAS-status, acidulating bacteria should have commercial potential. For example, perhaps an extract of growth from a culture of *Acetobacter* spp. would have potential as a preservative with specific effectiveness against Gram-negative bacteria.

12.2.3 Protective Cultures and Probiotic Cultures

Protective Cultures

The term *protective culture* can be used to identify a strain or a mixture of strains added to a food for the primary purpose of improving safety of the product without changing the sensory characteristics of the food.[112] This distinguishes a protective culture from a starter culture, in that the starter culture is used to bring about intended compositional and sensory changes in a food (ie, a fermented food). Enhanced product preservation or an antimicrobial effect can be considered an associated benefit. Therefore, one culture can function as a starter culture or a protective culture depending on the allowed level of microbial activity in the food. As described above, Microgard® could be termed an example of a protective culture with the bacteria prevented from further metabolic activity by pasteurization. Pas-

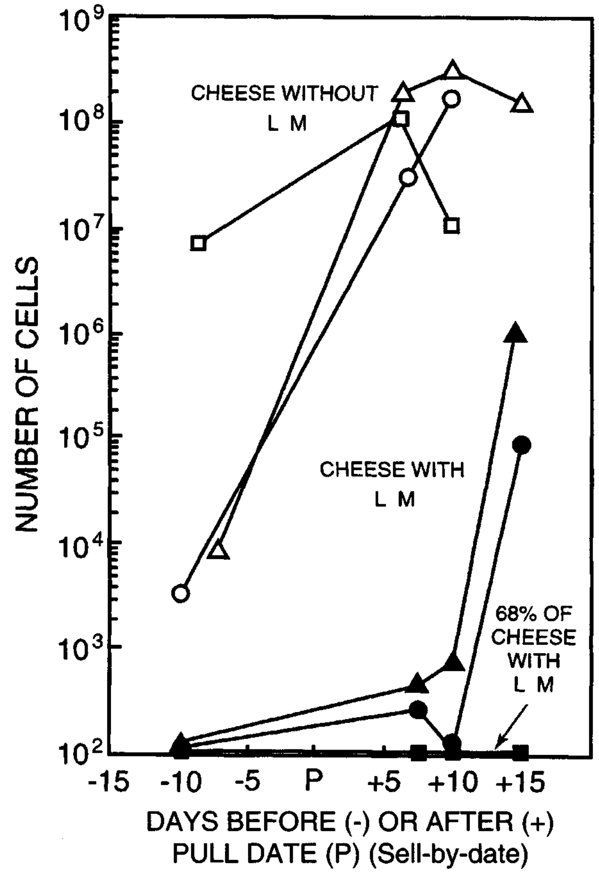

Figure 12-2 Inhibitory Effect of Liquid Microgard® (LM) against Spoilage Gram-negative Bacteria of Commercially Produced, Refrigerated Cottage Cheese. Open symbols represent three control groups without LM and closed symbols represent three test cheese groups with 1% LM. The cottage cheese was stored at 7°C for up to 30 days. *Source:* Reprinted with permission from M.A. Salih, W.E. Sandine, and J.W. Ayres, Inhibitory Effects of Microgard on Yogurt and Cottage Cheese Spoilage Organisms, *Journal of Dairy Science,* Vol. 73, pp. 887–893, © 1990, American Society of Animal Science.

teurization would not be a requirement for use of all protective cultures, but should the culture not be impaired or inactivated in some manner, a change in storage conditions of the product could result in revived culture metabolism in the food with possible deterioration of the sensory quality, such as over-acidification.

The Wisconsin Process for the preservation and safety of bacon with reduced levels of sodium nitrite employs a protective culture of *Pediococcus acidilactici.*[245] Sodium nitrite is an effective inhibitor of *Clostridium botulinum*; however, upon cooking, sodium nitrite in meat can form carcinogenic nitrosamines. The Wisconsin Process was devised to produce bacon as antibotulinal as regular bacon, but with lower levels of sodium nitrite. In this process, bacon is made with 40 to 80 ppm sodium nitrite, *P. acidilactici,* and 0.7% sucrose. This bacon has the same shelf life and sensory quality as regular bacon made with 120 ppm sodium nitrite.[244,245] If Wisconsin Process bacon is temperature abused, the protective culture grows and metabolizes the sugar to produce acid and other inhibitory compounds to prevent growth of, and toxin production by, *C. botulinum*. Excessive temperature abuse results in a soured but safe product.

Probiotic Cultures

Another category of microorganisms used as food additives is probiotic cultures. In this case, one can view the site of biocontrol as the human gastrointestinal tract. With the rise in consumer awareness of individual health, nutrition, and well-being, the interest and demand for value-added foods and beverages with enhanced nutritional benefit continues to expand. Rapid growth is anticipated in the American marketplace for cultures used as "nutriceuticals"; by 2010 industry analysts predict this market will grow about six-fold to $50 billion per year.[82] Terms such as nutriceuticals and functional foods are used to describe foods or components of foods that can prevent and treat diseases.[86] Use of these terms infers that in addition to its nutritive value, a functional food is consumed as part of the diet and not in supplement form (eg, capsule or tablet). It is a food derived from naturally occurring ingredients, and has a defined beneficial function when ingested. These functions may include the enhancement of the body's defense mechanism, prevention or recovery from a specific disease, the control of physical and mental conditions, and slowing of the aging process. Probiotic cultures are a category of nutriceuticals: viable cultures added to foods with the intent of maintaining or improving the nutritional health of the consumer.

The concept of ingesting viable, beneficial lactic acid bacteria in foods and beverages for improvement in general health and nutrition has existed since the turn of the century.[116] The major proponents were Elie Metchnikoff and his associates at the Institut Pasteur in the years before World War I. Currently, the favored groups for use as therapeutic human dietary adjuncts are the lactobacilli and bifidobacteria, although human probiotic preparations incorporating enterococci, propionibacteria, and *Saccharomyces* strains have been developed.[150]

Health benefits suggested from the regular ingestion of probiotic cultures are improvement of lactose digestion, treatment of diarrhea, serum cholesterol reduction, cancer suppression, immune system stimulation, treatment of constipation, and treatment of vaginitis.[219] Additional benefits are deconjugation of bile salts, stimulation of peristaltic movement, control of mucin at the intestinal surface, metabolism of ammonium ions, aid in absorption of calcium, and synthesis of vitamins.[114] Exhibit 12-1 lists these suggested benefits and others. Many opinions exist as to the general effectiveness of lactic acid bacteria and other acidulating bacteria in the promotion of human health. Further clarification is required for many of these claims to achieve wide acceptance by regulatory agencies and the general public.

One of the indicated benefits of regularly ingesting probiotic cultures is the antagonistic action against acid-sensitive enteric pathogens with maintenance of a lower fecal pH and a more stable equilibrium of the intestinal microbiota. Production of antimicrobial products by probiotic cultures represents a mechanism for maintaining a healthy gut equilibrium and is one of the desired properties for a good probiotic strain.[78,88,218] Although the mode of action for a positive probiotic effect is very complex and is often unclear, the mechanisms in which probiotic cultures are assumed to act are competition versus other bacteria for nutrients and for adhesion receptors on the gut epithelium and stimulation of immunity and production of antibacterial substances.[79] Therefore, in addition to the production of antimicrobial substances and conditions effective against detrimental gut bacteria, other desirable strain characteristics involve culture maintenance and viability, and consumer safety. These traits would be represented by good *in vitro* growth, minimal loss of culture viability during product storage, stability after exposure to acids and bile salts, and safety for human use that usually implies toxicological studies or long-recognized GRAS status and original isolation and abundance in the human intestinal tract.[218]

Exhibit 12-1 Suggested Benefits of Ingesting Bifidobacteria and Other Probiotic Cultures

- Stabilization of intestinal microbiota
- Induce cell-mediated immunity
- Anti-tumorigenic
- Reduce serum cholesterol
- Aid digestion, especially of lactose
- Deconjugation of bile salts
- Stimulate peristaltic movement
- Control mucin at intestinal surface
- Degrade nitrosamines
- Metabolize ammonium ions
- Aid in absorption of calcium
- Vitamin synthesis
- A key to infant nutrition
- Treatment of some diarrheas
- Intestinal recolonization following antibiotic treatment, chemotherapy, or radiation treatment
- Prevent vaginal yeast infections

Renewed interest in probiotic application has caused more intense study of the bifidobacteria. Once identified as lactobacilli, bifidobacteria continue to draw attention as human probiotics due in part to the production of acetic and lactic acids from fermentable sugars and their natural predominance in the human colon. However, probably more of a basis for selection of bifidobacteria for development as probiotic agents has been the early documentation of high levels of bifidobacteria in fecal samples from breast-fed infants as compared to weaned or bottle-fed infants.

Bifidobacteria can be isolated from feces of humans at any age. At birth, bifidobacteria are one of the first groups to establish themselves in the intestinal tract and usually are the largest group represented in infants. For breast-fed babies, levels of 10^{10} to 10^{11} per g of feces are common.[171] Bifidobacteria constitute over 25% of the intestinal flora in healthy breast-fed infants, while lactococci, enterococci, and coliforms represent less than 1% of the population, and bacteroides, clostridia, and other organisms are absent.

In comparison, bottle-fed babies normally have 1-$\log_{10}$ count less bifidobacteria present in fecal samples than breast-fed babies, and bottle-fed infants generally have higher levels of Enterobacteriaceae, streptococci, and anaerobes other than bifidobacteria.[171] With the change of diet and the aging process following infancy, the level of bifidobacteria declines so that Bacteroidaceae predominate in the adult gut, with eubacteria, bifidobacteria, and Peptococcaceae represented in that order. The superiority in overall health of breast-fed infants compared with bottle-fed infants is fairly well established, therefore the associated findings of high numbers of acidulating bifidobacteria relative to other bacteria in the gut imply a contribution of *Bifidobacterium* to this state. Results from fecal counts are often affected by the type and number of volunteers contributing fecal samples, diet, and sample analysis and interpretation.

Another approach to attain elevated levels of gut bifidobacteria is the ingestion of prebiotic substances (with or without probiotic cultures).[83] Such prebiotic compounds are bifidogenic factors that stimulate proliferation of resident bifidobacteria while the growth of undesirable bacteria, such as clostridia, is not enhanced. In the 1950s, it was commonly believed that human milk was a requirement for the growth of bifidobacteria. It is now established that a range of compounds can act as bifidogenic substances and the early emphasis on mother's milk as a source of bifidogenic substances was overestimated. In *Bifidobacterium*, growth requirements and growth-promoting factors vary from species to species. Most of the bifidogenic compounds identified are amino sugars that occur in human colostrum or other natural sources.[173] For some species of *Bifidobacterium*, bovine casein digest and yeast extract have been reported to have a more consistent growth-promoting effect on bifidobacteria than human milk whey.[195] Other examples of bifidogenic compounds are lactoferrin, lactulose, lactitol, and oligosaccharides.[12] Fructo-oligosaccharides have received much attention, especially in Japan where they have become a common food additive.[172] Bifidogenic fructooligosaccharides such as inulin can be obtained from Jerusalem artichokes, chicory, and Dahlia roots.

Bifidobacteria and lactic acid bacteria can be used clinically to treat diarrheal diseases and intestinal infections, especially in the very young and very old.[46,121,171] For example, Saavedra et al.[215] have presented strong evidence for the prevention of diarrhea and shedding of rotavirus by feeding infants a milk formula supplemented with *Bifidobacterium bifidum* and *Streptococcus thermophilus*. The double-blind, placebo-controlled study not only demonstrated a reduction in the incidence of acute diarrhea and rotavirus shedding in 55 subjects, but the probiotic formula was also well tolerated by the children, many of whom were initially malnourished or immunocompromised because of underlying disease. In a similar Japanese study with a powder containing 10^9 to 10^{10} g^{-1} of *Lactobacillus casei*, favorable results were indicated from a subject pool of 32 infants ($\leq$1-year-old) suffering from rotavirus enteritis.[239] These data suggest probiotic microbial preparations may provide a practical method for the prevention of diarrheal disease in a wide range of clinical and environmental conditions.

Other clinical trials have involved the influence of probiotic feeding on the metabolic (ie, enzymatic) activity of the resident microbiota. A significant reduction in the fecal activities of bacterial ß-glucuronidase, azoreductase, and nitroreductase was found with the administration of *Lactobacillus acidophilus* isolated from humans.[87] In another human feeding study,[158] fermented dairy products containing high numbers of *B. bifidum* and *L. acidophilus* caused a substantial decline in fecal nitroreductase activity, however, no significant decrease in ß-glucuronidase or azoreductase activity occurred. The yogurt cultures, *S. thermophilus* and *L. bulgaricus*, have been shown in a human feeding study[191] to have no effect on fecal enzyme activities; however, ingestion of *Lactobacillus gasseri* for 12 days dramatically decreased all three enzyme activities in fecal samples. Such measurement of fecal enzyme activities give an approximation of the alteration of intestinal metabolism in a beneficial manner. Clearly, this effectiveness is dependent upon the type of probiotic cultures used. Several probiotic preparations decrease fecal enzyme activity[150] and imply a decrease in the mutagenicity of the intestinal contents.[151]

In the last 10 years or so, a significant momentum of activity has occurred in the study of bacteriocins from lactic acid bacteria and other acidulating GRAS bacteria that have potential application in foods and beverages as "natural" preservatives. The information generated in the study of food-grade bacteriocins can potentially be used to genetically improve probiotic cultures in an effort to improve the antimicrobial nature of these strains in the human gut. Conversely, bacteriocins discovered from clinical isolates of probiotic cultures have the potential for development as commercial food preservatives.

12.3 BACTERIOCINS

12.3.1 History and Microbial Ecology

The earliest workers in microbiology recorded antagonism between competing microorganisms.[113] In 1676, Antonie van Leeuwenhoek first documented antibiosis, observing that the product from one microorganism inhibited the growth of another. In 1877, Pasteur and Joubert recorded the inhibition of common bacteria from urine against *Bacillus anthracis*. In the 20th century, the mechanisms for these events began to be revealed and antibiotic substances, including antibacterial peptides and proteins, were shown to play an important role in microbial interaction and competition.

Originally the term "bacteriocin" developed with emerging information from study of the colicins, which were the prototype bacteriocins. Their activity was first described by Gratia in 1925; "principe V" was produced by one strain of *Escherichia coli*

Next Page

against another strain of *E. coli*. The term "colicine" was coined by Gratia and Fredericq in 1946.[164] Later, "bacteriocine" was used by Jacob et al.[124] as a general term for highly specific antibacterial proteins. The term colicin now implies a bactericidal protein produced by varieties of *E. coli* and closely related Enterobacteriaceae.[146] Therefore, bacteriocins were originally defined as bactericidal proteins characterized by lethal biosynthesis, a very narrow range of activity, and adsorption to specific cell envelope receptors.[124] Following further study, a later amendment was the association of bacteriocin biosynthesis with plasmids.[241] While there is no universally accepted definition, the term has now been generalized and expanded to encompass the differences between colicins and bacteriocins produced by Gram-positive bacteria. Today, all antibacterial peptides and proteins produced by bacteria are referred to as bacteriocins. In addition, a broader range of target bacteria is now incorporated into the definition along with the allowance that the peptides and proteins can contain other functional moieties, such as carbohydrates or lipids.[71,131]

Bacteriocin-producing bacteria can be isolated from a wide range of habitats; most if not all Gram-positive and Gram-negative bacteria produce bacteriocins.[216] It has been estimated that 40% of all strains of *E. coli* produce a colicin.[113] Given this commonality, it would appear bacteriocins offer bacteria an added adaptability or competitive advantage against other bacteria for location, food, and other resources.[71] It has been shown that bacteriocin-producing lactobacilli will persist longer and outcompete nonbacteriocin-producing lactobacilli in olive fermentations.[214]

In lactic acid bacteria as well as many other types of bacteria, depletion of the transmembrane proton motive force is the common mechanism of bactericidal and bacteristatic activities by bacteriocins.[24,30,31,40] In an intact, functioning membrane, there is a net proton gradient with a proton flow out of the cell, which causes the outer side of the membrane to have a positive charge and the inner side to have a negative charge. It appears that most bacteriocins form pores or ion channels in the cytoplasmic membrane resulting in loss of ions and the collapse of the proton gradient; this disrupts the generation of energy and causes death, injury, or inhibition of growth. Although this mode of action among bacteriocins appears widespread in nature, there is a broad range of molecular weights representing a divergent evolutionary response to the diversity of competing species.[71] While some colicins can form ion channels in the cytoplasmic membrane, colicins E2 and E3 and cloacin DF13 are enzymes; E3 and DF13 have RNase activity and E2 has restriction endonuclease activity.[154,199]

With the keen interest in developing bacteriocins as natural food preservatives for commercial application, the practical concern has arisen about the concurrent development of spontaneous bacteriocin resistance similar to that seen with the proliferation of antibiotic-resistant bacteria in response to increased use of therapeutic antibiotics. Populations of bacteriocin-sensitive bacteria will naturally contain bacteriocin-resistant varieties.[170] Presently, it is not certain whether immunity to bacteriocins will spread in the same manner and timetable as has immunity to commonly used therapeutic antibiotics.

Over the past several years, the increased interest in bacteriocins has generated a number of valuable review papers, books, and book chapters written to describe and review activities of the bacteriocins or of the antimicrobial action of bacteria with relationship to foods.[65,98,115,123,142,143,146,203,204,241] Exhibit 12-2 consolidates most of the key reasons for recent interest in bacteriocins produced by lactic acid bacteria.

Exhibit 12-2 Events Contributing to the Increasing Number of Applied Investigations on Bacteriocins from Lactic Acid Bacteria and Bacteriocinogenic Lactic Acid Bacteria

- Safe and efficacious use of nisin during the past 30 years.
- Food and Drug Administration (FDA) approval of nisin as a GRAS substance in certain applications.
- Consumer resistance to traditional "chemical" preservatives and a desire for "natural" preservation.
- Justifiable concerns over the safety of existing food preservatives such as nitrates and sulfites.
- Realization that bacteriocinogenicity is not a rare occurrence in lactic acid bacteria.
- Feasibility of using bacteriocin production and immunity as selectable genetic markers in starter culture bacteria.
- Availability of molecular biology techniques to transfer, clone, and sequence the genetic determinants and to engineer genetic determinants of bacteriocins.
- Willingness of federal funding agencies, food commodity groups, and food processing corporations to fund both basic and applied research.

Source: Reprinted with permission from M.A. Daeschel, Applications and Interactions of Bacteriocins from Lactic Acid Bacteria, in *Bacteriocins of Lactic Acid Bacteria,* D.G. Hoover and L.R. Steenson, eds., pp. 63–91, © 1993, Academic Press, Inc.

The bacteriocins from lactic acid bacteria are now categorized into four classes[143] (Exhibit 12-3). Lantibiotics (class I) are small membrane-active proteins that contain lanthionine amino acids (hence their name). Nisin is an example; subtilin from *Bacillus subtilis* has a common ancestry with nisin and is also a lantibiotic. Class I can be subdivided into subtypes A and B.[137] Nisin and subtilin are included in subtype A; this group features amphiphilic polypeptides, which are elongated and cationic, and act by disruption of proton motive force at the cytoplasmic membrane. Examples of subtype B are duramycin and cinnamycin. These bacteriocins are neutral, globular, amphiphilic polypeptides acting as enzyme inhibitors and immunoadjuvants. Class II bacteriocins from lactic acid bacteria include small heat-stable membrane-active nonlanthionine peptides. Leucocin A is a representative bacteriocin. Large heat-labile proteins such as helveticin J constitute class III. Plantaricin S is an example of class IV, containing complex bacteriocins with carbohydrate or lipid moieties.

12.3.2 Nisin

Nisin remains the current focal point by which all bacteriocins intended for use as biopreservatives are compared for potential commercial and regulatory acceptance. This ribosomally synthesized peptide has an established track record of performance as a food additive on the world market, and therefore has accumulated the greatest amount of practical information. Nisin has a documented record of safety in foods.[118] The activity of nisin was first observed in 1928.[211,212] It was named by Mattick and Hirsch[162] from "N inhibitory substance," because the industrial cheese starter cultures, group N dairy streptococci (now *Lactococcus lactis*) not only produced nisin, but nisin-negative strains were inhibited by it. Nisin was first used as a food preservative in 1951,[109] and in 1969, the Joint Food and Agriculture Organization/World Health Organization (FAO/WHO) Expert Committee on Food Additives gave nisin international acceptance.[260] In the United States (US), it is presently the only bacteriocin permitted for use in foods as a food additive.[74] While other bacteriocins from lactic acid bacteria are receiving attention in the search for other applicable GRAS biopreservatives, nisin remains the preeminent model system for these types of compounds.

Exhibit 12-3 Classes of Bacteriocins from Lactic Acid Bacteria

Class I—Lantibiotics (heat stable)
Examples: nisin, lactocin S, lacticin 481, carnocin UI49

Class II—Small (<15,000 Da) heat-stable nonlantibiotic peptides
Examples: leucocin A, diplococcin, lactacins B and F, lactocin 27, lactococcin A, sakacins A and P, curvacin A, enterocins E1A and 1146, plantaricin SA6, pediocins, carnobacteriocins

Class III—Large (>15,000 Da) heat-sensitive proteins
Examples: helveticins J and V-1829, lacticins A and B, caseicin 80, acidophilucin A

Class IV—Complex bacteriocins with nonproteinaceous components
Examples: plantaricin S, leuconocin S

There are several natural variants of nisin, all with 34 amino acids. The size of the pentacyclic monomeric form of nisin is approximately 3,500 daltons with dimer and tetramer forms common.[119] As noted earlier, nisin is grouped in the class of bacteriocins known as lantibiotics; besides subtilin,[126] other examples of lantibiotics are epidermin,[5] gallidermin,[140] cinnamycin, and duramycin.[92] The composition of nisin features the unusual amino acids, dehydroalanine, dehydrobutyrine, lanthionine, and ß-methyllanthionine[93] (Figure 12-3); however, peptide antibiotics that contain unusual amino acids are common.[95,96] Gramicidin S and valinomycin are two such examples that are synthesized by nonribosomal mechanisms, whereas nisin undergoes a novel sequence of posttranslational modifications of ordinary amino acids.[120] The sequence of the gene encoding for nisin production and its flanking regions have been elucidated.[32,68,138]

A majority of the genes for bacteriocins from Gram-positive bacteria are linked to plasmids. In the case of *nisA*, the structural gene for the nisin precursor has been associated with a 70-kb conjugative transposon.[69,202] Siegers and Entian[228] identified three open reading frames belonging to the nisin gene cluster of *L. lactis* 6F3, which also appear to be involved in the immunity of the nisin-producing strain to nisin. In this strain, the complete gene cluster for nisin biosynthesis is 15 kb. The gene *nisG* encodes for a hydrophobic protein, which probably acts similarly to the immunity proteins already described for several colicins.

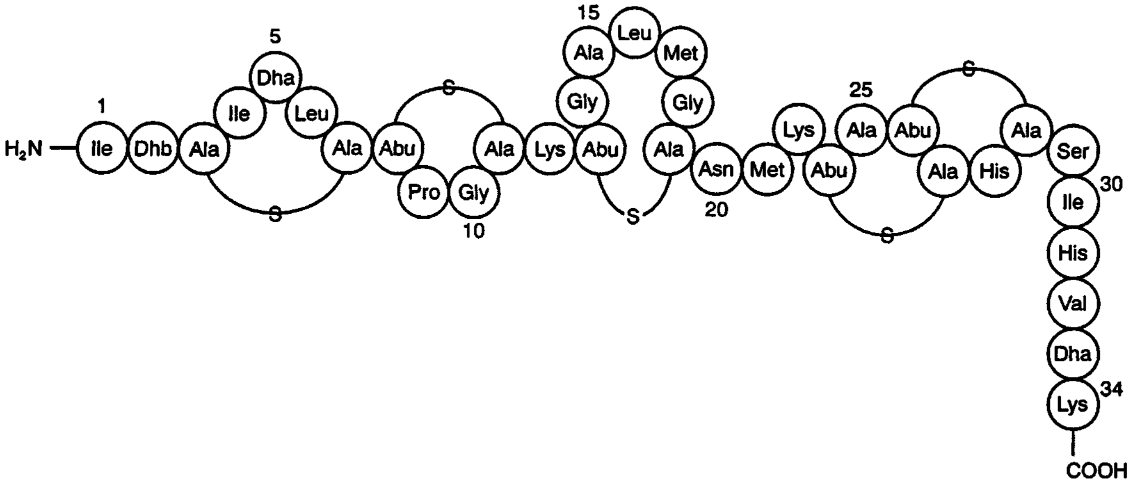

Figure 12-3 Nisin A. *Source:* Reprinted with permission from D.G. Hoover, Bacteriocins: Activities and Applications, *Encyclopedia of Microbiology,* Vol. 1, pp. 181–190, © 1992, Academic Press, Inc.

The techniques of protein engineering have been applied to nisin. Two mutants of nisin Z (a natural nisin variant) were found to have similar antimicrobial activity, but improved solubility at neutral pH and stability to pH and temperature.[213] In the nisin mutants, a lysyl residue replaced either an asparagine and a histidine in the primary sequence of nisin Z.

Target bacteria for the action of nisin include most Gram-positive genera, although the sensitivity of Gram-positive bacteria varies. Nisin-negative lactococci are susceptible as well as other lactic acid bacteria. Nisin-sensitive genera that contain important foodborne pathogens are *Listeria, Staphylococcus, Clostridium,* and *Bacillus.* Normally, Gram-negative bacteria are not sensitive to nisin; however, if the outer lipopolysaccharide layer is removed or absent from the cell boundary, the cytoplasmic membrane is no longer protected from the effects of nisin and such Gram-negative bacteria become nisin sensitive.[234,235] Compared with bacteriocins from other lactic acid bacteria, nisin has a rather broad spectrum of activity; however, when compared with therapeutic antibiotics, the range of activity of nisin is quite small. Nisin is not inhibitory against yeasts and molds.

Nisin is also quite effective against the spores of Gram-positive bacteria. This is a valuable characteristic because the endospores of Gram-positive bacteria are so resistant to heat and other methods used to process and preserve foods. In the US, nisin was approved for use in pasteurized, processed cheese spreads because of its effectiveness against gas-forming spoilage clostridia (ie, "blowing" faults caused by *Clostridium butyricum* and *C. tyrobutyricum*). Just as vegetative cells vary in sensitivity to nisin, so do bacterial spores. The spores of the small-spored species of *Bacillus* (eg, *B. subtilis*) are more sensitive to nisin than those of the large-spored species (eg, *B. cereus*).[90]

Spores of *C. sporogenes, C. butyricum,* and *C. bifermentans* have been shown to be much more sensitive to nisin than the respective vegetative cells.[108] Against *C. botulinum,* nisin is a more effective inhibitor of type E than type A; the range of nisin concentrations necessary to inhibit outgrowth from spores of *C. botulinum* is from 100 to 5,000 IU and in addition to strain type inhibition is dependent upon spore concentration and the medium or food examined.[225,226] To prevent spore outgrowth, it has been suggested that nisin covalently modifies the sulfhydryl groups of proteins of newly germinated spores.[97,175]

Nisin has been evaluated in a variety of foods and beverages; sometimes a valuable preservative effect is evident, but sometimes there is limited or no observable benefit.[66] For the antibiotic effect of nisin to be realized, nisin must be added to the product as a food additive or growth extract, or a nisin-positive culture of *Lactococcus lactis* subspecies *lactis* must actively grow in the product, as in the production of a fermented food. No nisin synthesis takes place during the stationary phase of the producing culture.[117]

Probably the greatest application for nisin as a food preservative is in milk and dairy products. This is only fitting given the commercial use of lactococci in cheese-making. Indeed, one of the early reports about inhibitory streptococci involved milk in which cheese starter organisms failed to develop.[259]

Many types of cheeses are susceptible to clostridial problems; Hirsch et al.[109] first used a nisin-positive starter culture in the making of Gruyère cheese to prevent undesirable clostridia from forming gas and butyric acid defects. Hawley[102] was the first to suggest that nisin be added to cheese milk as a mixture with powdered skim milk, a common practice today. The commercial preparation, Nisaplin®, is marketed in powdered form containing 2% active nisin with the remainder inert ingredients, notably nonfat dry milk and sodium chloride. To prevent significant loss in the whey, it is recommended that nisin be added after the lactic fermentation at concentrations of 40 to 400 IU g^{-1}. Of course, using nisin in this manner requires a nisin-resistant culture or a nisin-producing culture immune to the effects of nisin.[153] Another concern in using nisin is that nisin can interfere in the aging of cheeses by inhibiting bacteria important in flavor development. With the development of genetically engineered cheese starter cultures, it would seem that modifying industrial lactococcal strains for nisin synthesis and immunity along with proteinase activity for flavor development offers great potential for extended use of nisin.[27,77] This technology may be applied to other bacteriocins and culture characteristics as well.

Since the 1950s, nisin has worked well as a food additive in processed cheese products.[66,233] The addition of water and flavor compounds with heated mixing of the unripened curd allows survival and outgrowth of clostridial spores. Because no fermentation or late microbial flavor development occurs in the manufacture of processed cheese products, the disadvantages described above for ripened cheeses are absent. Levels of 100 to 250 ppm are normally used in these products. Somers and Taylor[233] examined the effectiveness of nisin in pasteurized process cheese spreads and found that in a cheese spread having a moisture content of 52% with 2.5% disodium phosphate but no added sodium chloride, 12.5 ppm nisin prevented outgrowth and toxin production by spores of *C. botulinum* (Table 12-1). It was suggested that the addition of nisin to cheese spreads (100 ppm or greater) can generate an equivalent antibotulinal effect while allowing for reduced sodium levels or somewhat higher moisture content compared with typical commercial pasteurized process cheese spreads.

Table 12-1 Toxicity Results on Process Cheese Spreads

% Na_2HPO_4	*Nisin (ppm)*	*Toxic Samples/ Total Sample #**
2.0	0	80/80
2.5	0	1/80
2.5	12.5	0/80
2.0	12.5	58/80
1.7	0	80/80
1.7	12.5	10/80
1.7	50	1/80
1.7	100	0/80

*Pasturized process cheese spreads were inoculated with approximately 10^3 g^{-1} spores of *Clostridium botulinum* and incubated at 30°C for up to 48 weeks. Toxicity was determined by the mouse injection assay.

In canned foods, nisin has been shown to increase the apparent heat sensitivity of bacterial endospores and to increase the efficiency of thermal processing, allowing for shorter times and lower temperatures to be used to attain commercial sterility.[37,38] Kiss et al.[141] showed in a pilot-plant study that 200 IU nisin ml^{-1} added to peas in jars permitted about a 60% reduction in the heat process resulting in an improved sensory quality of the peas. In those parts of the world where energy use is inconsistent or costly, the savings derived from the addition of nisin to low-acid canned foods for reduction of the energy costs of thermal processing offers a satisfactory return on the cost of nisin. It should be emphasized here that nisin is not employed in an antibotulinal role, but as an anti-thermophile agent for acid foods or for neutral-pH foods given a full antibotulinal cook.

Nisin at levels of 50 to 100 IU g^{-1} has been shown to be effective for a range of low-acid canned foods, such as vegetables, meats, seafood, mushrooms, dairy, and pasta products[76,153]; however, if the microbial quality of the product is poor, nisin will not mask deficiencies in good manufacturing practices. For example, even at high levels of 500 IU nisin g^{-1}, canned products such as soup, cream-style corn, and chicken chow mein will spoil if contaminated with heavy bacterial loads.[103,104,129]

In high-acid canned foods of pH below 4.5–4.6, more acid-tolerant, thermophilic spoilage spore formers are the target in exploiting the synergy of nisin use with thermal processing. In these foods, the lower pH improves the solubility, stability, and activity of nisin. Against spoilage bacteria, such as *Bacillus coagulans* and *Clostridium thermosaccharolyticum*, nisin concentrations of 50 to 200 IU g^{-1} can prevent spoilage in beans packed in tomato sauce, canned tomato products, and canned fruits.[38,62,104,252]

The results of using nisin and other bacteriocins in meats have not been very successful. The solid nature and composition of meats cause uneven distribution and binding or "neutralization" of nisin. At the neutral pH of most meat products, the solubility and stability of nisin is low, limiting its effectiveness. These factors result in an inconsistent preservative action of nisin against Gram-positive food pathogens and spoilage agents, even at extremely high levels of nisin. Against spores of proteolytic strains of *C. botulinum*, nisin concentrations from 1,000 to 5,000 IU g^{-1} were ineffective, even when used in combination with low levels of nitrite and mild acidification.[207,232] Similar results were obtained versus other spore formers and nisin-resistant lactic acid bacteria.[18,36,128] A disadvantage in using nisin for extension of the shelf life of meat products is that the metabolism and growth of psychrotrophic and mesophilic Gram-negative bacteria play an important role in spoilage of these products, but nisin alone has little effect on these bacteria. To deal with Gram-negative bacteria, Shefet et al.[227] combined nisin with food-grade chelating agents (EDTA, citric acid, and Tween 20) to extend the shelf life of broilers stored under refrigeration. *Salmonella typhimurium* inoculated onto fresh broiler drumstick skin was reduced by 3- to 5-$\log_{10}$ after a 30-minute immersion in a solution of nisin and chelating agents.

Recently, Einarsson and Lauzon[72] compared nisin Z with two other bacteriocins, carnocin UI49 (from *Carnobacterium piscicola* UI49) and bavaricin A (from *Lactobacillus bavaricus* MI 401). Nisin Z was more effective than the other two bacteriocins in the preservation of chilled brined shrimp, extending the shelf life of the shrimp 31 days beyond the preservative-free control. Carnocin UI49 showed no preservative effect, while bavaricin A extended the shelf life 16 days. However, 0.1% benzoate-sorbate solution preserved the brined shrimp for the entire storage period of 59 days.

In some cases, nisin is effective as an adjunct when combined with nitrite and other preservative agents or treatments[206,207]; however, in all these adaptations incorporating nisin, the cost of nisin plays a very important role in its commercial acceptance and use. Currently, chemical preservatives and mild heat treatments for meat products can usually be applied as effectively and more cheaply than nisin alone or as a processing aid. Under these circumstances, nisin often cannot compete economically. Future use of nisin and other bacteriocins will depend heavily on consumer reaction to the adjective "natural" in product labeling.

Usually the spoilage bacteria targeted for inactivation by nisin are the Gram-positive spore formers and the lactic acid bacteria. Lactic acid bacteria are sometimes a problem in the manufacture and preservation of alcoholic beverages. In wines, nisin can be used at 100 to 1,000 IU ml^{-1} to regulate uncontrolled malolactic fermentation caused by nonstarter pediococci, leuconostocs, and lactobacilli as well as other spoilage defects caused by lactic acid bacteria. Daeschel et al.[51] used nisin-resistant varieties of *Leuconostoc oenos* with 100 IU nisin ml^{-1} to regulate the malolactic fermentation in wine. In the maintenance of brewers' yeast, the use of nisin to wash the pitching yeast to rid it of unwanted lactic acid bacteria is recommended over the traditional harsher method of acid washing.[185] The nisin treatment effectively eliminates lactobacilli from the yeast starter culture, but leaves the *Saccharomyces* with improved viability and unchanged fermentative performance. Because *Saccharomyces* is unaffected by nisin, this can be added to the wort to prevent contaminated fermentations caused by lactic acid bacteria that produce off-flavors and other defects.[186] Nisin survives pasteurization, filtration, and fining in the making of malted beverages, and can be added after the yeast fermentation as a means of maintaining quality and enhancing flavor by allowing a reduction of heat treatment.

12.3.3 Bacteriocins Produced by Acidulating Gram-positive GRAS Bacteria

Other Bacteriocins Produced by Lactococci

Because the bulk of literature and product development concerns nisin, other bacteriocins produced by lactococci are sometimes overlooked. Contributing to this may be that diplococcin also has a long history (as far as bacteriocins are concerned), but has several inherent characteristics that severely curtail its development as a biopreservative. Produced by a minority of strains of *Lactococcus lactis* subspecies *cremoris*, diplococcin becomes very unstable when purified, has a limited spectrum of antagonistic activity (eg, it is ineffective against spore formers), and has a relatively high degree of sensitivity to trypsin, pronase, α-chymotrypsin, and most importantly, heat.[54,187] Initially, one might expect that diplococcin would be very similar to nisin because these bacteriocins are produced by two closely related subspecies of lactococci with demonstrated effects against other lactococci. Such is not the case; nisin is more closely related to subtilin produced by *B. subtilis*. Diplococcin is larger in size (5,300 daltons) and is not a lantibiotic; it does not contain lanthionine, ß-methyllanthionine, dehydroalanine, or dehydrobutyrine.[57] Instead of having potential commercial benefit in foods, diplococcin is a problem in that cheese-makers must be aware of diplococcin-producing lactococci that can rapidly predominate over other lactococci used in multiple-strain starter cultures.[56] In *L. lactis* subspecies *cremoris*, Davey[55] characterized an 81-kb conjugative plasmid harboring diplococcin synthesis and immunity, while Neve et al.[183] demonstrated conjugation of the ability to produce diplococcin with a 60-kb plasmid.

Another lantibiotic produced by *L. lactis* subspecies *lactis* that has been characterized is lacticin 481, a highly hydrophobic polypeptide of 23 amino acids.[192] Lacticin 481 is more closely related to streptococcin A-FF22 produced by *Streptococcus pyogenes* FF22 than nisin.[122,193] Although exhibiting a narrower spectrum of activity than nisin, lacticin 481 may have application as a preservative in cheese products as it has shown strong activity against *Clostridium tyrobutyricum*, is resistant to heat and rennet, and, unlike nisin, is stable at neutral pH.[192]

Nearly all *L. lactis* subspecies *diacetylactis* strains and some *L. lactis* subspecies *cremoris* and nonnisin-producing *L. lactis* subspecies *lactis* strains produce bacteriocins referred to as lactostrepcins.[147] Antagonism has been demonstrated against other lactococci, streptococci (groups A, C, and G), *Bacillus cereus*, and some *Lactobacillus* and *Leuconostoc*.[265] Lactostrepcins are group I bacteriocins that are heat stable (121°C for 10 minutes) and approximately 10,000 daltons. A pH ≤ 5.0 is required for optimal activity, but their effectiveness is limited because of their sensitivity to proteolytic enzymes, phospholipases, and lipases.[14,67]

Lactococcins is a term that can be used to encompass all the bacteriocins produced by *Lactococcus*: nisin, diplococcin, lacticin 481, the lactostrepcins and others, although in some cases the term is directly applied to the less characterized lactococcal bacteriocins eg, lactococcins A, B, and M. Different strains of the three lactococcal subspecies can produce the same lactococcins, although the plasmids encoding the bacteriocins display different sizes and profiles among these strains.[111,221,249,250] Holo et al.[111] has purified and characterized lactococcin A, a small, hydrophobic polypeptide produced by *L. lactis* subspecies *cremoris* LMG 2130 that is effective only against other lactococci.

Lactobacilli

The lactobacilli are a very heterogeneous group composed of a rich diversity of related microorganisms. Early work with specific bacteriocin activity in *Lactobacillus* was done by De Klerk and coworkers,[59–61] although the general inhibitory effect of the growth of lactobacilli was studied in the late 1940s with dairy lactobacilli.[94,253,258] Bacteriocin activity was suggested during this period, lactobacillin from *Lactobacillus delbrueckii* subspecies *lactis* was named by Wheater et al.[256,257]; however, as discussed earlier, it can be difficult to separate bacteriocin activity from the other antibacterial substances and conditions produced by lactic acid bacteria. Throughout the 1970s, the antagonistic activities of lactobacilli were often poorly characterized. Inhibition by lactobacilli was commonly demonstrated against a wide array of Gram-positive and Gram-negative bacteria; some inhibition could be eliminated or reduced by adjustment to neutral pH or by treatment with catalase, indicating that organic acids and hydrogen peroxide made significant contributions to the inhibition. Most bacteriocins from lactobacilli inhibit only other lactobacilli.

Since the 1980s, Klaenhammer and coworkers have closely examined the genetics and biochemistry of several bacteriocins from *Lactobacillus*. Lactacin B is produced by *L. acidophilus* N2.[16] Lactacin B forms aggregates; the molecular weight of the monomer is 6,000 to 6,500 and aggregates are as large as 100,000 daltons.[17] Lactacin B is bactericidal against other lactobacilli, *L. bulgaricus, L. helveticus, L. leichmannii,* and *L. lactis*, and heat stable (100°C for 1 hour). Synthesis and immunity are apparently chromosomally located as *L. acidophilus* N2 lacks plasmid DNA.

L. acidophilus 88 produces lactacin F.[16] Lactacin B and lactacin F are chemically very similar, although in addition to the lactacin B indicators, Muriana and Klaenhammer[180] found lactacin F antagonistic against *Lactobacillus fermentum* and *Enterococcus faecalis*. Also, unlike lactacin B, lactacin F is plasmid encoded, associated with plasmids of approximately 6 and 40 kb. Genetic analysis of transconjugants indicated the involvement of transient plasmid determinants capable of chromosomal insertion, suggesting that the detectable plasmids were the result of a defective or incomplete mobilization event. Further study by Muriana and Klaenhammer[181,182] revealed lactacin F to be a micelle-like globular particle with a molecular weight of 180,000. Amino acid analysis estimated a peptide of 56 amino acids (~7,500 daltons); SDS-PAGE analysis approximated a size of 2,500 daltons. Purification of lactacin F is extremely difficult due to its highly hydrophobic nature. Lactacin F is extremely heat stable (121°C/15 minutes), which is indicative of a small hydrophobic peptide lacking tertiary structure. Indeed, lactacin F is so heat stable that it can easily be used as a selective agent in autoclavable bacteriological media to select transconjugants in matings employing lactacin F production and immunity as markers.[144] Lactacin F probably acts at the cell membrane.

Helveticin J differs from lactacins B and F. This bacteriocin is more closely related to caseicin 80[201] and acidophilucin A.[246] These bacteriocins are large and sensitive to inactivation by heat and have not been extensively studied. Helveticin J has a limited range of antagonistic activity, inhibiting some strains of *L. helveticus, L. bulgaricus,* and *L. lactis.* Joerger and Klaenhammer[133] concluded that like lactocin 27, the genes for production and immunity of helveticin J reside on the bacterial chromosome. At neutral pH, *L. helveticus* 481 produces helveticin J, which forms aggregates of over 300,000 daltons, but with purification, a protein of 37,000 daltons can be identified that retains functionality. Later work by Joerger and Klaenhammer[134] resulted in the cloning and sequencing of the structural gene for helveticin J.

Lactocin 27 is produced by *L. helveticus* LP27 and appears very similar to the bacteriocin produced by *L. fermenti* 466 and studied by De Klerk and Smit.[61] Lactocin 27 was originally described as a protein-lipopolysaccharide complex of over 200,000 daltons[247]; however, purification yielded a glycoprotein of 12,400 daltons.[248] Heat stable with no demonstratable loss of activity after 1 hour at 100°C, lactocin 27 is bacteriostatic against *L. helveticus* LS18 by inhibiting protein synthesis and by interfering with sodium and potassium transport.

West and Warner[255] found bacteriocin activity in *Lactobacillus plantarum* 1193, but the bacteriocin, plantaricin B, was not isolatable from liquid culture. Sensitive to proteolytic enzymes, antagonistic activity was reduced upon exposure to lipase and α-amylase. Inhibition occurred against selected lactic acid bacteria. *L. plantarum* C11 was found to produce plantaricin A.[52] It is similar to plantaricin B, in that the inhibitory effect is against other lactic acid bacteria, members of *Lactobacillus, Leuconostoc,* and *Pediococcus.* Plantaricin A is heat stable (100°C/30 minutes) and active over a pH range of 4.0 to 6.5. The purification and partial amino acid sequence of plantaricin S was recently reported.[132] Purification from the crude growth extract increases antibacterial activity of plantaricin S over 350,000-fold. Full activity of plantaricin S is dependent upon two distinct peptides, α and ß, that have apparent sizes of 26 and 24 amino acids, respectively. They have no apparent homology with each other.

Schillinger and Lucke[224] screened 221 strains of lactobacilli isolated from meat and found 23 of them to exhibit bacteriocin-like activity. From this work, *L. sake* Lb 706 was found to produce sakacin A, which shows considerable variability in its efficacy against target bacteria. Lactic acid bacteria and strains of *Listeria monocytogenes* and *Listeria innocua* are sensitive to the bactericidal action of sakacin A, but this sensitivity is highly dependent on the individual strain.[223] Antagonistic activity remains unaffected after a 20-minute exposure to 100°C, but all activity is eliminated after 20 minutes at 121°C. Sakacin A is a single polypeptide chain of 41 amino acids with a molecular weight of 4,309. Holck et al.[110] have sequenced sakacin A. These workers also found the structural gene for the bacteriocin residing on a 60-kb plasmid encoding for a primary translation product of 59 amino acids that is shortened to 41 amino acids. In the N-terminal end, sakacin A has a very close sequence homology with other nonlantibiotic bacteriocins from lactic acid bacteria.[222] Given its effectiveness against *L. monocytogenes, L. sake* Lb 706 and sakacin A have been recommended for use in fermented meats and meat products.

Lactocin S is produced by *L. sake* L45, a culture isolated from a meat fermentation by Mortvedt and Nes.[176] The bacteriocin is moderately heat stable and effective against selected Gram-positive bacteria, most of which are lactobacilli and other lactic acid bacteria. Lactocin S is composed of 33 amino acids.[177] Its structural gene is plasmid linked.[176] Two plasmids of approximately 50 and 34 kb are associated with production and immunity; however, there is variability between the plasmid genotype and the phenotypic characteristics, suggesting transpositional elements that cause instability and rearrangement of the genes. Recently, Mortvedt-Abildgaard et al.[178] reported on the activity and production of lactocin S. The pH of the culture was a key parameter in the inactivation of target cells. At pH >6.0, lactocin S-sensitive cells were unaffected by the presence of lactocin S. Production of lactocin S by *L. sake* L45 was eliminated by aerobic conditions, but anaerobically, production was increased 8- to 10-fold when pH was maintained at 5.0 in a fermentor compared with batch cultures. The addition of 1% ethanol to the growth medium resulted in a 2- to 4-fold increase in yield of lactocin S.

Carnobacterium and Leuconostoc

The genus *Carnobacterium* has been distinguished from *Lactobacillus*[45] and represents the atypically nonaciduric lactobacilli indigenous to refrigerated meats. Carnobacteria have been shown to produce bacteriocins with the potential for commercial development.[236] The bacteriocins produced by *Carnobacterium piscicola* LV17 are of interest because activity is detected early in the growth cycle.[2,3] Carnobacteriocin A is produced from a plasmid, pCP49 and carnobacteriocin B from pCP40 in *C. piscicola* LV17.[4] A third bacteriocin may be present in this strain.[236] The bacteriocins from *C. piscicola* LV17 are bactericidal against other lactic acid bacteria, enterococci, and *Listeria* spp. The bacteriocins are heat stable (100°C/30 minutes) and stable over a broad pH range (2–11).

Carnocin UI49 is a bacteriocin from a strain of *Carnobacterium* isolated from fish.[238] Amino acid analysis of the 4,635-dalton peptide suggests that carnocin UI49 belongs to the lantibiotic class of bacteriocins, making UI49 distinct from the bacteriocins produced by *C. piscicola* LV17 that do not contain lantibiotic-like amino acids.

Members of *Leuconostoc* are heterofermentative lactic acid bacteria commonly associated with fermented vegetables and cultured dairy products. Like carnobacteria, leuconostocs can predominate on chill-stored meats packaged with elevated levels of carbon dioxide.[227] Leucocin A is produced by *Leuconostoc gelidum* UAL 187.[101] The 3,930-dalton peptide is heat resistant (62°C/30 minutes) and inhibitory against lactic acid bacteria, *E. faecalis*, and *Listeria monocytogenes*. As with *C. piscicola* LV17, *L. gelidum* UAL 187 produces bacteriocin early in its growth cycle, but can additionally produce leucocin A during growth at 1°C. Mesenterocin 5 is produced by *Leuconostoc mesenteroides* UL5.[48] While mesenterocin 5 is a heat stable (100°C/30 minutes) 4,500-dalton peptide effective against *L. monocytogenes*, it is not produced early in growth.

Given the limitations of nisin and nisin-producing lactococci in meats, carnobacteriocins and bacteriocins from *Leuconostoc* have been suggested for development for storage extension and enhanced safety of chill-stored meats.[237] Although effective against most strains of *L. monocytogenes*, bacteriocins of *Carnobacterium* and *Leuconostoc* have a limited spectrum of activity. A bacteriocin with a broader antibacterial spectrum would be preferable.[236] Other disadvantages include a minimum pH for the synthesis and release of bacteriocins above the pH of the meat, and gas or dextran production by leuconostocs. An important advantage is that these bacteria are adapted to the intended products so growth and activity in the chilled meat products could occur. Certainly, the genetic engineering of carnobacteria and leuconostocs isolated from meat with more functional bacteriocin genes from other bacteria would have potential in this area. Allison et al.[6] recently introduced the lactacin F operon from *Lactobacillus johnsonii* VPI 11088 into *C. piscicola* LV17. The transformants of *C. piscicola* LV17 expressed lactacin F as well as the native carnobacteriocins, demonstrating that the machinery for carnobacteriocin production is capable of processing and exporting bacteriocins from both systems. Similarly, van Belkum and Stiles[251] introduced lactococcin A production (from *Lactococcus lactis* subspecies *cremoris*) into leucocin A-producing *Leuconostoc gelidum* UAL187 showing that lactococcin A could be exported by the leucocin A-secreting machinery.

Pediococci

Homofermentative pediococci serve as commercial meat starter cultures in the production of fermented sausages and have been found to produce bacteriocins with possible use as food preservatives. For example, pediocin AcH from *Pediococcus acidilactici* inhibits a much wider range of bacteria than bacteriocins from *Carnobacterium* and *Leuconostoc*. In addition to lactic acid bacteria and listeriae, pediocin AcH inhibits species and strains of *Bacillus* (both spores and vegetative cells), *Clostridium* (both spores and vegetative cells), *Staphylococcus*, *Propionibacterium*, and *Enterococcus*, as well as *Brochothrix thermosphacta*.[23] As shown with nisin, the bactericidal effect is dependent upon the ratio of the concentrations of the bacteriocin and the target organisms. Inhibition by pediocin AcH is highly variable within species of a genus and among strains of the same species. In each sensitive strain, some cells are resistant to pediocin AcH, ie, the percentage that is strain variable. Pediocin AcH acts on vegetative cells by membrane destabilization and upon spores by preventing outgrowth following germination.[205]

Both pediocin AcH and pediocin PA-1[89] are well-studied bacteriocins produced by different strains of *P. acidilactici*. Recently, they have been found to be the same peptide.[205] PA-1 is a simple protein of 44 amino acids (4,629 daltons) with two disulfide bonds.[105] Produced by *P. acidilactici* PAC 1.0, pediocin PA-1 is encoded by a 9,400-kb plasmid. Deletion analysis from cloning and expression in *E. coli*[161] revealed a 5,600-kb fragment necessary for pediocin PA-1 synthesis. Four open reading frames were found, of which two were characterized. The first encoding for the 62-amino acid precursor with amino acid residues 19 to 62 corresponding to the purified bacteriocin, and the fourth open reading frame specified a large protein of 724 amino acids required for pediocin PA-1 production in *E. coli* that probably corresponded to an ATP-dependent transport protein. Comparison of the amino acid sequence of pediocin PA-1 with leucocin A-UAL, lactacin F, and lactococcins A, B, and M found few sequence similarities except for the N-terminal leaders of amino acids 18 to 24 of the precursor proteins, particularly near the cleavage site. This site is uniquely conserved in the precursors of bacteriocins from lactic acid bacteria, suggesting the requirement for different processing enzymes in the maturation of small heat-sensitive bacteriocins produced by lactic acid bacteria.

A mixture of dried powder of growth extract from *P. acidilactici* PAC 1.0 and 10% nonfat dry milk was used[198] for evaluation as a preservative against the growth of *L. monocytogenes* LM01 in cottage cheese, half-and-half cream, and cheddar cheese soup for two weeks at 40°C. The mixture showed effective preservative effects over a pH range of 5.5 to 7.0 against 10^2 to 10^3 cfu g^{-1} of *L. monocytogenes* in the foods.

A new bacteriocin from pediocococci was recently described.[42] Produced by *P. acidilactici* L50 that was isolated from Spanish dry-fermented sausages, pediocin L50 shows a wide range of activity. It was effective against all Gram-positive bacteria tested; target organisms included members of *Bacillus, Clostridium, Staphylococcus, Listeria,* and *Propionibacterium*. Pediocin L50 is heat stable (100°C/40 minutes). It appears to contain modified amino acids but not lanthionine or methyllanthionine.

With pediococci used extensively as meat starter cultures, the efficacy of bacteriocin-producing pediococci has been evaluated in various model meat systems. Examples include Nielsen et al.[184] who examined radiation-sterilized fresh lean beef muscle inoculated with *L. monocytogenes* Scott A and treated with filter-sterilized extract from growth of a bacteriocin-producing commercial meat culture of *P. acidilactici.* The bacteriocin reduced the attachment of *L. monocytogenes* to the meat surface. The bacteriocin was functional on meat surfaces after a month of refrigerated storage. Berry et al.[20] challenged *L. monocytogenes* Scott A (inoculated at 10^8 cfu g^{-1}) with *Pediococcus* spp. strains JD1-23 and MP1-08 in summer sausage chubs and found a reduction of 2 $\log_{10}$ using a bacteriocin-producing culture and a reduction of 1 $\log_{10}$ with a bacteriocin-negative culture of *Pediococcus*. In a later study with frankfurters,[21] bacteriocin-producing *P. acidilactici* was deemed effective against *L. monocytogenes.* In the making of dry fermented sausages, bacteriocin-positive *P. acidilactici* PO2 eliminated a mixture of five strains of *L. monocytogenes* (inoculated at 10^5 cfu g^{-1}) when the pH at the end of the fermentation was <4.9.[75] To improve the effectiveness of pediocin AcH, Degnan and Luchansky[58] encapsulated the bacteriocin with phosphatidylcholine liposomes and found almost a 30% improvement in bactericidal effect versus *L. monocytogenes* in heated slurries of beef and beef tallow compared with slurries amended with free pediocin.

Propionibacterium and Bifidobacterium

The propionibacteria are not closely related taxonomically to the lactic acid bacteria used in foods; however, on a functional basis they display similar traits and thus have become valuable in food fermentations. Members of the genus *Propionibacterium* metabolize carbohydrates or lactic acid to propionic acid, acetic acid, and carbon dioxide.[15] They are aerotolerant anaerobes that function in the production of the nutty flavor and "eyes" of Swiss-type cheeses, serve as probiotics and silage adjuncts, in rum fermentations, in production of propionic acid from whey and manufacture of vitamin B_{12} as well as the food preservative, Microgard®.

Propionibacterium theonii P127 produces propionicin PLG-1.[155] Inactivated by exposure to 85°C for 30 minutes, the bacteriocin is stable at pH 3 to 9 with its greatest activity at pH 7.0. Unlike most other bacteriocins from GRAS acidulating bacteria, propionicin PLG-1 (9,300 daltons) inhibits a range of Gram-positive and Gram-negative bacteria, and some yeasts and molds. Microorganisms affected by PLG-1 include most propionibacteria, lactococci, lactobacilli, pediococci, pseudomonads, and some *Saccharomyces* strains, *Candida lipolytica,* and aspergilli. Glatz and coworkers have biochemically characterized and obtained the N-terminal sequence for PLG-1.[156,188]

Jenseniin G is produced by *Propionibacterium jensenii* P126.[91] It is heat stable (100°C/15 minutes) and active against dairy propionibacteria, lactococci, and lactobacilli. It has also been shown to be sporostatic against spores of *Clostridium botulinum.*[80] The lack of detectable plasmids in *P. jensenii* P126 suggests a chromosomal location for the gene(s) of jenseniin G.

Bifidobacteria are more closely related to propionibacteria than lactic acid bacteria. The major commercial use of *Bifidobacterium* is as a probiotic culture, as discussed earlier. Jao et al.[127] implied that the antibacterial effect of *Bifidobacterium bifidum* may be caused by the production of antibacterial substances in addition to acids. Anand et al.[8] found possible bacteriocin activity in *B. bifidum*, although cultures of Gram-positive and Gram-negative bacteria were inhibited by growth supernatants below pH 4.5 and fractionated metabolites singly or in combination did not display activity. Meghrous et al.[168] partially characterized a bacteriocin from an unspeciated *Bifidobacterium*. Active between pH 2.0 and 10.0 and heat resistant (121°C/15 minutes), lactic acid bacteria and clostridia were inhibited.

Streptococcus and Enterococcus

Bacteriocins STB 40 and STB 78 have been described from *Streptococcus thermophilus*, one of the two primary commercial yogurt-producing cultures.[231] These bacteriocins were heat stable, active in a pH range of 2.0 to 12.0, inactivated by proteolytic enzymes and by lipase, and estimated to be between 10,000 and 20,000 daltons. Inhibition was demonstrated against other strains of *S. thermophilus* and *Enterococcus*.

Bacteriocin St10 is only antagonistic toward other strains of *S. thermophilus*; it is produced by *S. thermophilus* St10.[41] It is heat stable (121°C/15 minutes), inactivated by α-amylase as well as proteolytic enzymes, and in its native state appears to have a molecular weight exceeding 100,000.

Thermophilin 13 is produced by *S. thermophilus* Sfi 13.[157] It is heat stable (100°C/1 hour), active in the pH range of 1.6 to 10.0, and is a peptide of about 4,000 daltons.

Enterocins, bacteriocins from *Enterococcus*, have been known for some time.[28,145] They are effective versus *L. monocytogenes*.[165] For example, enterocin E1A is bactericidal to strains of *L. monocytogenes* and other enterococci.[148] Enterocin 1146 (produced by *E. faecium* DPC1146) has shown a very strong and widespread effectiveness against *L. monocytogenes*, and against all *Listeria* tested[189,190]; however, enterocin 1146 can be inactivated by exposure to 60°C, especially at a pH approaching neutrality. Nonetheless, in an acidic food at the levels of *L. monocytogenes* naturally found in contaminated foods, there is potential for the addition of *E. faecium* DPC1146 to a fermented product as an adjunct to the normal starter culture(s).[107] A mutant of *Enterococcus faecalis* INIA 4, a bacteriocin-producing strain, has been adapted as a preservative agent against *Listeria innocua* in raw milk cheeses.[135]

12.4 CONCLUDING REMARKS

This chapter presented an overview of the antimicrobial compounds and conditions produced by microorganisms with importance or potential importance in the preservation of foods and beverages. In this area over the past decade, bacteriocins have received the greatest amount of interest and subsequent laboratory research. However, work continues to evolve and mature with the blending of old and new antimicrobial methods and components in modern-day food processing. Certainly, major advances in food preservation are likely to be seen with the application of the recombinant methods involving genetic engineering and protein engineering in microbiology, but these advances will be optimized for compatibility and synergy with other developments in food processing. Examples of these other somewhat nontraditional areas in food preservation include the use of nonmicrobially derived enzyme systems and components, irradiation, active packaging systems that possess antimicrobial activity and biosensors for enhanced product safety, minimally processed chilled food technology and cold pasteurization methods (eg, hydrostatic pressure processing and pulsed light treatment). Consumer demand continues for highly nutritious, fresh-like foods that possess a high margin of safety usually associated with heavily processed foods. Having this contradiction to ameliorate puts the onus on food scientists to be innovative in the preparation and delivery of safe, high quality food products. These requirements usually necessitate a specific blend of processing methods and aids for each category of product. Therefore, with the growth in the complexity and scope of food laws and product regulations, future developments for the use of microbially derived preservatives and protective cultures should be even more product specific than what is seen in current practice. Of course, the success of any new product or technology is determined in the marketplace. A new preservative must not only be effective for its intended purpose, but do so at an economically feasible cost. That has proven an imposing barrier for many new and innovative preservative methods.

13.1 INTRODUCTION

The main preservation techniques used currently act in one of three ways: (1) preventing access of microorganisms to foods, (2) inactivating them should they have gained access, or (3) preventing or slowing down their growth should they have gained access and not been inactivated. However, there has been increasing interest in modifying these approaches, or in developing new ones, with the objective of reducing the severity of the more extreme techniques. While many such developments have involved new uses of existing techniques in new combinations to inhibit the growth of microorganisms (hurdle technology) (see Chapter 14), the new developments have also included radically new physical procedures aimed at inactivating microorganisms in foods. While the mechanisms of action of some of the new procedures are well understood at the cell physiology or molecular levels, understanding of others remains empirical.[27]

The techniques mostly aim to offer full or partial alternatives to heat. They include the use of high hydrostatic pressure (ultrahigh pressure), high voltage electric discharges (electroporation), high-intensity laser or noncoherent light pulses, high-intensity magnetic field pulses, and the combination of mild heating with ultrasonication and slightly raised pressure (manothermosonication). Of these, the first (hydrostatic pressure) has captured a niche market that is continuing to grow. The other techniques remain to be exploited or to have their commercial viability proven.

13.2 HIGH HYDROSTATIC PRESSURE

13.2.1 Background

High hydrostatic pressures, above about 100 MPa (1 MegaPascal is equivalent to about 9.87 atmospheres; 10 bar; 0.1 kgf cm^{-2}; 145 lbf $inch^{-2}$), were originally shown to inactivate vegetative bacteria by Hite[48] nearly a hundred years ago and by workers[49] (reviewed by Heden[46]) at the beginning of the 20th century. Spores were found to be much more resistant, surviving pressures above 1,200 MPa.[6,72] These early studies also demonstrated that pressure treatment extended the keeping quality of some foods, including milk,[48] fruits, and vegetables.[49] However, technological constraints prevented commercial use of pressure for food decontamination until the 1980s.[77] At this time, engineering techniques had advanced to the extent that industrial processes were developed for the pressure pasteurization of a number of low pH foods, in which spores were not a problem, including jams, fruit juices, jellies, sauces, and fruit for yogurt,[113] dressings, and ingredients for ice creams.[68] At the same time, because pressure affects macromolecules (eg, denaturing proteins and modifying polysaccharide gels to bring about textural changes that differ from those caused by heat), the technology is presenting new opportunities for novel food texturization.[14,63,77] More recently, therefore, there has been a rapid expansion in research into the engineering technology, microbiology, materials science, and other food science aspects of pressure pasteurization.[68] This was followed by the introduction of new pressure-pasteurized foodstuffs (eg, chill-stored guacamole, dairy, fish, and meat products[89]), including some that have higher pH values than the jams and fruit juices that were marketed originally. The outlook for pressure-treated foods is widely expected to grow, probably through the capture of selected small-volume, high-value, niche markets rather than high-volume commodity markets.

13.2.2 Pressure Delivery

The use of high pressure for food processing involves the application of pressure isostatically, ie, the pressure is equal thoughout the material being processed. The procedures used are referred to as *cold isostatic processing* (CIP). These derive from forming techniques used in the metals, ceramics, carbon/graphite, and plastics industries, and they utilize pressures in the range from about 50 to about 600 MPa at near ambient temperatures. CIP contrasts with WIP (warm isostatic processing), which is another forming technique that operates at temperatures up to about 200°C and has not been found relevant to food processing. Hot isostatic processing (HIP) employs pressures up to about 400 MPa at temperatures as high as 2,200°C and is used in the metals and ceramics industries.

Pressure is applied conventionally, either directly by forcing liquid into the treatment chamber or indirectly by forcing a piston into the liquid-filled vessel containing the food. There is a transient temperature rise associated with pressurization, amounting to about 11C° at 400 MPa and 23C° at 800 MPa (for water[29]). The temperature rise dissipates at a rate dependent on the volume of the treatment chamber, its construction materials, and the conductivity of the surroundings, etc. High pressure processing of foods in the first commercial systems to be developed operates as a batch process with treatment times commonly between about 0.5 and 5 minutes. The economics of the process demands fast cycling times and the highest pressures possible, currently up to about 600 MPa, commensurate with the avoidance of metal fatigue, too-frequent seal failure, etc.[77] These requirements pose substantial engineering challenges that have been met with a number of innovative approaches to vessel design, and that require regular replacement schedules for sensitive parts, for laboratory scale equipment,[30] and for commercial use.[21,77,85]

The volumes of commercial treatment vessels are currently between about 50 and about 1,000 L.[5] Larger capacity vessels are mostly limited to operating pressures lower than those capable of inactivating microorganisms in foods. True continuous processes are not yet used commercially, though cost-effective semicontinuous systems that can be used with pumpable liquid products have been developed.[5,81]

In contrast to the situation with thermal processing, the applied pressure is transmitted instantaneously and uniformly throughout the the treatment vessel and product being treated. No pressure gradients are established during the process. Product to be treated is normally enclosed in sealed packages, which are sufficiently flexible to withstand the compression that occurs during pressurization. The pressure medium surrounding the packs (usually water mixed with a small amount of oil for lubrication and additives to prevent corrosion of the steel vessels, pistons, and valves) and the packs and pack contents, are compressed to about 80% to 90% of their original volumes during pressurization in the 400 to 800 MPa region but, of course, return to their original volumes when the pressure is released.

13.2.3 Mechanism of Action

The effects of high pressure derive from the Le Chatelier principle.[40] Pressure favors any physical or chemical reaction in which there is a net volume decrease and suppresses any reaction in which there is a net volume increase. In kinetic terms, reactions with a negative activation volume will be accelerated while those with a positive activation volume will be retarded. In complex systems, such as a foodstuff or a microbial cell, in which many reactions take place, the overall effects will therefore depend on these terms rather than on the more familiar free energy or activation free energy that form the basis for the major effects of heat. With reference to biological systems, the most important volume-decrease reactions include the denaturation of proteins, gelation, hydrophobic interactions, phase changes in lipids (and therefore in cell membrane structure), and increases in the ionization of dissociable molecules resulting from electrostriction.[47] Small molecules are therefore generally less affected than macromolecules, so that low molecular weight (MW) flavor and odor compounds in foods tend to survive the pressure used to process them relatively unchanged, with consequent retention of high organoleptic quality of some types of foods (eg, jams).[55] On the other hand, the high MW components of some foods (eg, proteins in meat, fish, and eggs) change greatly on pressurization, and the changes that occur, particularly in texture, may or may not be desirable.[63]

It is clear therefore from the known action of pressure on molecules and chemical reactions that a structure as complex as a microorganism will contain a number of pressure-sensitive components and targets for lethality, eg, key enzymes, genetic material, and molecular assemblies such as ribosomes and membranes.[59] It is therefore not surprising that pressure induces a variety of changes in vegetative microbial cells,[54] eg, in the morphology of yeast mitochondria and cell walls and other subcellular structures and in cell wall–cell membrane interactions in bacteria.[67,70] Pressure caused changes in fatty acid composition and in the protease and lipase activities of *Yarrowia lipolytica*.[71] Many cellular enzymes will, of course, be affected by pressure. The effect of pressure on 13 metabolic enzymes produced by strains of *Listeria monocytogenes* varied greatly,[116] but did not correlate with barotolerance of the strains.[117] An important specific example includes membrane-bound Na/K ATPase.[16] Loss of this enzyme may play a part in the inactivation of vegetative bacteria by pressure through interference with pH homeostasis and consequent acidification of the cytoplasm.[119] However, the multiple effects of pressure make the existence of a single key site for pressure inactivation unlikely.

The situation regarding bacterial spores is different from that with vegetative cells. Ungerminated spores are very pressure tolerant,[106] but there is a region of pressure-temperature combinations where pressure directly causes spores to germinate.[16,37] This occurs even in the absence of any nutrients or chemical "germinants." Having been germinated by pressure, the germinated spores may then survive if the pressure and/or temperature are low enough or be inactivated if they are high enough. The combination of possibilities leads to a peculiar pattern of spore response to pressure in which relatively low pressures may be more sporicidal than higher ones under some circumstances (see below).

Regarding mechanisms of spore tolerance to high pressure, it was very reasonably suggested that this most likely resulted from protection of spore proteins by the low state of hydration of the cytoplasm in the spore protoplast.[123] The mechanism of action of pressure-induced germination is less clear. Its kinetics suggested a physiological basis, such as a shift in the equilibrium of a Donnan phase somewhere within the spore.[17] It has been proposed that the extreme dormancy of spores may result in part from their low water content protoplasts being in a glassy state[36] and that pressure, like temperature, would affect its stability. A glassy state was proposed, with some supporting kinetic evidence, to explain in part the heat resistance of spores.[110] Limited studies indicate that viruses have high tolerance to pressure.[14]

13.2.4 Effects on Microorganisms

Vegetative Cells

Kinetics. While the earliest studies of the effects of pressure on microorganisms showed that vegetative cells in milk, meat, fruits, and vegetables could be inactivated at about 300 MPa and above, there were few data on the kinetics of inactivation and the levels of kill achievable. More detailed studies have been made recently and, although some examples of exponential kinetics have been reported for the inactivation of vegetative cells held at constant pressure (eg, *Escherichia coli*),[11,74] the majority of studies have found "tails" on survivor curves (ie, a decreasing death rate with time of treatment) (Figure 13-1).[26,79,93] It has been suggested that a reason for these apparent discrepancies is that at higher temperatures (eg, 40°C and above for *E. coli* at 250 MPa) inactivation is near first order whereas at lower temperatures (eg, 30°C for *E. coli*) it is nearer to second order. It was proposed that temperature-dependent changes in lipid composition may account for these differences and, indeed, phase changes in membrane lipids have been shown to occur at around 30°C in *E. coli*.[28]

Temperature, Water Activity, and pH. More generally, over the temperature range from +20°C to –20°C high pressure is more effective in inactivating vegetative microorganisms at the lower than the higher temperatures (eg, for *Lactobacillus casei* and *E. coli*[120] and for *Staphylococcus aureus, Salmonella bareilly*, and *Vibrio parahaemolyticus* in phosphate buffers[122]). Likewise, *Citrobacter freundii* in minced beef was more pressure sensitive at 4°C than at 20°C (a 10^6-fold reduction was caused by pressurization at 280 MPa for 20 minutes at 20°C, but 230 MPa caused

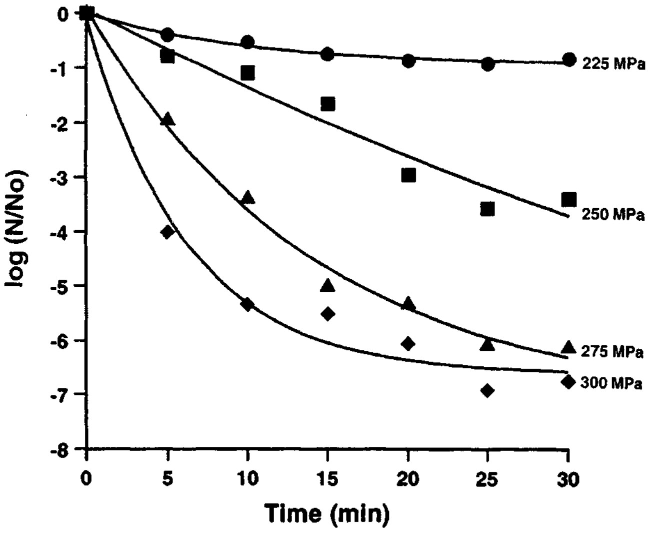

Figure 13-1 Nonlinearity of Pressure Survivor Curves. *Yersinia enterocolitica* in pH 7 phosphate-buffered saline at 20°C. *Source:* Reprinted with permission from M.F. Patterson et al., Effects of High Pressure on Vegetative Pathogens, in *High Pressure Processing of Foods,* D.A. Ledward, D.E. Johnston, R.G. Earnshaw, and A.P.M. Hasting, eds., pp. 47–63, © 1995, Nottingham University Press.

the same reduction at 4°C[12]). It has been suggested that, in addition to any direct effects (eg, on the fluidity of membrane lipids etc), low temperature may prevent metabolic adaptation to pressure and so minimize any rise in tolerance occurring during the period of holding under pressure.[26]

While salt solutions have been reported to reduce the pressure resistance of some vegetative microorganisms in buffers,[23] effects in foods are more complex. Generally, it has been found that substantial reductions in water activity (a_w), achieved by the addition of a range of solutes (including sucrose, glucose, and fructose, of relevance in the pressure pasteurization of jams, as well as sodium chloride) led to increases in pressure tolerance, eg, of *Rhodotorula rubra*.[88] While pH over the range 3 to 8 did not influence the pressure inactivation of this organism, raising the treatment temperature to 45°C allowed a satisfactory pasteurization process to be achieved at 400 MPa. The low pH– and low a_w–tolerant yeast, *Zygosaccharomyces bailii,* which frequently spoils products such as mayonnaises, pickles, and fruit concentrates, was reduced more than 10^6-fold by treatment at 345 MPa at 21°C for 5 minutes when the a_w was higher than 0.98. However, at lower a_w, achieved by the addition of sucrose, the level of inactivation was much less, eg, about 10^2-fold at a_w 0.92.[91] The baroprotective effect of reduced a_w was described by a linear relationship between $(1 - a_w)$ and the log of the surviving fraction.

Influence of Food and Strain. There are a number of examples where the pressure tolerance of a particular microorganism varies greatly in different media or foods, for reasons that remain unclear (Figure 13-2). For example, *Salmonella typhimurium* was inactivated about 10^6-fold in pork meat by a 10 minute pressure treatment at 300 MPa whereas only a 10^2-fold reduction was achieved in a chicken baby food at the slightly higher pressure of 350 MPa.[79] *Listeria monocytogenes* was more resistant to pressurization in UHT milk than in phosphate buffered saline.[121]

Strain-to-strain variation in pressure sensitivity seems to be greater than the strain-to-strain variation in sensitivity to other inactivation techniques, such as heat. For example, *L. monocytogenes* 4b serotypes NCTC 11994, Scott A, and an isolate from chicken were inactivated by just less than 1 log, just over 2 logs, and about 5 logs, respectively, by pressurization at 375 MPa for 10 minutes at 20°C in 10 mM phosphate-buffered saline (Figure 13-3).[94]

Otherwise, exponential phase cells are more pressure sensitive than stationary phase ones.[23,59] Gener-

ally Gram-positive microorganisms are more pressure tolerant than Gram-negative ones.[115] For example, *Staphylococcus carnosus* was inactivated by less than 1 log by exposure to 400 MPa for 1 hour,[27] and evidence of recovery was seen in a rising count during continued pressurization. However, important exceptions to the generally observed lower resistance of Gram-negative bacteria have been observed (eg, *E. coli* O157:H7, see below).

Pathogens. Reported pressure sensitivities of foodborne vegetative pathogens in a variety of buffers, media, and foods were reported by Patterson et al.[93,94] Pressurization times were mostly within the range from 10 to 30 minutes and at temperatures near to 20°C. The most sensitive pathogen was *Vibrio parahaemolyticus*, with a 10^6-fold reduction at pressures as low as 170 MPa.[121] *Yersinia enterocolitica* and *Campylobacter jejuni* were similarly inactivated at 300 MPa[115] and *S. bareilly* (>10^8-fold) at 200 MPa.[122] Exposure to 300 MPa inactivated *Salmonella typhimurium* 10^6-fold as enumerated on selective agar[115] but less than 10^2-fold when enumerated on nonselective medium.[79] A similar pattern was found for *E. coli*.[59] *Salmonella senftenberg* 775W and *Salmonella enteritidis* were slightly more resistant, with 10^4- to 10^6-fold reductions at 350 to 500 MPa.[94] *L. monocytogenes* Scott A was inactivated 10^6-fold or more in a variety of media and foods at pressures ranging from 340 to 450 MPa. *S. aureus* was inactivated more than 10^8-fold in phosphate buffer at 400 MPa but only 10^4-fold in poultry meat and 10^2-fold in UHT milk at 600 MPa.[94] The organism most out-of-line with the general sequence of tolerance from Gram-negative to Gram-positive organisms was *E. coli* O157:H7 for which the very high pressure of 700 MPa was necessary to achieve a 10^6-fold reduction in phosphate-buffered saline and a 10^5-fold reduction in poultry meat (Figure 13-2). In UHT milk, even exposure at 800 MPa failed to affect more than a 10^2-fold reduction.[94]

Injury and the Effect of Stresses. The lower recovery of pressurized microorganisms on selective versus nonselective media referred to above illustrates that pressure can cause nonlethal injury that is only expressed under conditions of stress.[64] Such food-relevant stresses may include mild heating and reduced pH. A potentially useful stress has been shown to be the presence of a bacteriocin such as nisin or pediocin. These amplified the inactivation by pressure of *L. monocytogenes* Scott A, *E. coli* O157:H7, and *S. typhimurium*.[64] High pressure transiently sensitized *E. coli* to nisin and lysozyme.[44] Chitosans increased the effectiveness of high pressure against *E. coli, S. aureus*, and *Saccharomyces cerevisiae*.[92] Although normally lysozyme resistant, *E. coli* was more pressure sensitive in its presence than in its absence.[95] On the other hand, it has been shown that imposition of stress on microorganisms prior to pressure treatment may increase their subsequent pressure tolerance. For example, cycles of pressure treatment of *E. coli*, followed by growth of survivors, led to a population exhibiting increased pressure tolerance.[43] Sublethal heating (heat shock), as expected, raised the resistance of *S. cerevisiae* to subsequent heating at a higher temperature, but also raised its resistance to hydrostatic pressure.[60] Mutants of *S. cerevisiae* lacking the ability to accumulate trehalose and/or to synthesize certain heat-shock proteins, had lost the heat-shock response, as expected, but also became sensitive to pressure.[61] Mutants of *E. coli* with increased pressure resistance were isolated from pressure-treated cultures. The mutants were inactivated by no more than 2 logs at pressures up to 600 MPa (15 minutes at ambient temperature) whereas the wild type was inactivated to a greater extent at 420 MPa under the same conditions.[43]

Altogether these various influences of environment and to a lesser extent, temperature, mean that it is currently much more difficult to predict the exact effects on microbial survival of a particular pressure treatment in a particular food than, for example, a particular heat treatment. Furthermore, the apparently large strain-to-strain differences in pressure tolerance make predictions for specific microorganisms even more difficult. Extensive *inoculated pack* studies remain necessary, particularly for low acid–high water activity foods in which the presence of pathogens is possible.

Spores

The extreme pressure tolerance of bacterial endospores was first demonstrated over half a century ago.[72] Pressures up to 1,200 MPa failed to inactivate spores of a number of species.[6,72,123] However, it was discovered later that, under certain conditions, inactivation of spores occurred more rapidly and completely at lower than at higher pressures.[17,106] These observations were difficult to reconcile with the expected effect of a physical treatment on a biological system: an increase in the intensity of a treatment would normally be expected to result in an increase in the degree of inactivation, comparably with heat, ultraviolet and ionizing radiations, electric shock, ballistic disintegration, etc.[102]

An explanation for the peculiar effect of pressure was found when it was observed that inactivation of spores occurred in two stages.[17,37] First, pressure caused the spores to germinate. Second, pressure inactivated the germinated forms. Spores of some species could be caused to germinate by pressures as low as a few tens of MPa, too low to inactivate the germinated forms. Under these conditions, the effect of pressure was therefore nonlethal, but brought about the normal range of sensitivities that are associated with spore germination (eg, to heat and to irradiation). This led to exploration of the combined use of pressure in combination with raised temperature[106] or with low dose ionizing radiation[127] to achieve a higher level of spore inactivation.

The fact that there was an optimum pressure for germination meant that as the pressure was raised above the range that caused the most rapid germination, the germinative effect was lost. However, the germinative effect of pressure was found to be very temperature dependent, so that the effect of combining pressure and temperature was complex, with an overall pattern like that shown in Figure 13-4A. If, following the release of pressure, the treated spores were subjected to a mild pasteurization heat treatment (eg, 70°C for 30 minutes), then a further fall in count occurred as a result of heat inactivation of the spores that had been germinated but not inactivated by the particular pressure-heat combination treatment (Figure 13-4B). Recent studies have confirmed the efficacy of pressure-temperature combinations in synergistically inactivating a wide range of spore types.[45,65,69,75,83,114]

Spores in sodium phosphate buffer (100 mM, pH 8) were pressurized for 30 minutes at 25° (○), 35° (●), 45° (□), 55° (■), 65° (△) and 75°C (▽). (**A**) Direct count after depressurization. (**B**) Counts after a post-pressurization heat treatment at 70°C for 30 minutes. *Source:* Reprinted with permission from A.J.H. Sale, G.W. Gould, and W.A. Hamilton, Inactivation of Bacterial Spores by Hydrostatic Pressure, *Journal of General Microbiology,* Vol. 60, pp. 323–334, © 1970, Society for General Microbiology.

Pressure cycling has been suggested as one approach to increase the inactivation of spores. Six 5-minute cycles of oscillating pressure at 600 MPa and 70°C reduced *Bacillus stearothermophilus* spore numbers by 6 logs.[45] However, others have found that the effect of pressure on spores results mainly from integrated time at pressure rather than on the act of raising or lowering pressure.[106,114]

The kinetics of germination/inactivation of spores of *Bacillus pumilus* by pressure was near exponential,[18] but spores of *Bacillus coagulans, Bacillus subtilis,* and *Clostridium sporogenes* held at constant pressure and temperature showed nonlog/linear inactivation kinetics, most often with concave-upward curves or long tails.[106]

Although the mechanism by which pressure causes germination is not yet known, it appears to be physiological in being most effective at near-neutral pH values and inhibited by extremes of pH when pressures are low, though *B. coagulans* spores were shown to be more pressure sensitive at pH 4 than at pH 7 at high pressure (400 MPa).[101] Pressure germination is inhibited at low water activities, most effectively if the low a_w is achieved by high concentrations of ionic solutes, such as NaCl, rather than nonionic ones, such as sucrose and glucose.[106] The germinative effect of pressure is increased by low levels of the physiological germinants such as L-alanine, inosine, and glucose, which are specific triggers for the germination of different types of spores. Pressure germination is inhibited by inhibitors that prevent such physiological germination.[37] However, as the pressure and temperature are raised in combination treatments, the pressure effects become dominant and added germinants and inhibitors exert less and less influence. The relationship of germination to pressure tolerance was further illustrated by the isolation of pressure-resistant mutants of *B. subtilis*. These were found to be not only pressure tolerant, but also defective in one of the known physiological germination systems (the *alanine pathway*) at ambient pressure.[129]

While Figure 13-4, which summarizes data obtained with *B. coagulans*, represents the pattern of response shown by all types of spores that have been studied, the exact levels of inactivation depend also on food-specific parameters such as pH, a_w, and nutritional status. Furthermore, the sensitivity of spores of different species varies *greatly*. For example, spores of *B. cereus* were much more sensitive than those illustrated in Figure 13-4, while spores of *Clostridium botulinum*, *B. subtilis*, and *B. stearothermophilus* were much more resistant,[67] so that generalizations must be treated with caution.

The extreme resistance of some types of spores has so far prevented the use of pressure to sterilize foods.[53] All current commercial applications are *pressure pasteurization* processes. The use of pressure to achieve sterilization must await either the development of economically viable presses that operate at higher pressure and temperature combinations, or the development of some alternative effective combination techniques.[14] For example, it has been shown that, as with vegetative cells, the presence of bacteriocins such as nisin can enhance the effectiveness of pressure against spores, eg, of *B. coagulans*, particularly if coupled with reduced pH (from 7 to 4) and raised temperature.[101]

The antimicrobial effectiveness of CO_2 is enhanced at moderate pressures. Microbial numbers on fresh herbs were reduced over 10^5-fold by treatment at 55 MPa under CO_2,[39] but most likely due to cell disruption caused by the intracellular release of dissolved gas on the release of pressure rather than the direct effect of pressure itself.[73]

13.3 HIGH VOLTAGE ELECTRIC DISCHARGE

13.3.1 Background

Pasteurization of foodstuffs by electric fields was first described by Getchell in 1935.[34] It was shown that passage of an alternating current through milk inactivated microorganisms in it. This probably occurred mainly through heating, but it was claimed that additional nonthermal inactivation occurred as well. While the application of electric fields to heat foods has since become well established,[90] eg, through electrical resistance or "ohmic" heating[32] and microwave heating,[82] the use of electric pulses to effect nonthermal inactivation of microorganisms in foods was explored and exploited more recently.[13] At the same time, use of the technique at lower, nonlethal voltages has become established as the basis for *electroporation*, by which genetic material may be exchanged between protoplasted cells of microorganisms, plants, and animals.[84]

A method was patented in 1960 for inactivating microorganisms with an electric field.[22] Later studies demonstrated the inactivation of bacteria and yeasts and the lysis of protoplasts and erythrocytes.[107,108] Still later studies concentrated on varying the electrical parameters[56,57,58] and the effects of the medium/environment.[62,80] These studies led to the development of prototype and industrial scale devices in the late 1980s and early 1990s (see below).

13.3.2 Delivery of High Voltage Discharges

Electric fields may be delivered as oscillating, bipolar, exponentially decaying, or square wave pulses. Oscillatory pulses have been found to be the least effective, while the energy efficiency of square wave pulses results in them being more lethal than exponentially decaying ones. Bipolar pulses (ie, with a reversal in the polarity of the field) were more lethal than monopolar pulses because, it was presumed, rapid reversal in the direction of movement of charged molecules caused greater damage to cell membranes. Additional advantages of bipolar pulses are that they generate less electrolysis in foods and they are energy efficient.[99]

The strength of the electric field which, along with the size of the microbial cell, determines the potential difference that develops across the cell membrane, is more important than the duration of the pulse in determining the extent of inactivation. Consequently, it is generally most economic to raise the field strength as high as possible while reducing the duration of the pulses, without increasing the pulse energy.[38] On the other hand, from the practical point of view, the use of very high field strengths demands more complex and expensive engineering.[130]

As a result of these competing requirements, the more modern pulse-field devices employ field strengths from about 20 up to about 70 kV cm^{-1}, with pulse durations of between 1 and about 5 microseconds. Pulse repetition rates and overall treatment times are limited in order to minimize temperature rise in the food being treated. Repetition rates are commonly between 1 and up to 30 seconds or so at the higher voltage gradients. As a result of these requirements, the engineering objectives have been to design treatment chambers to hold foods in such a way that they receive near-uniform treatment, with pulses that are of short duration but have high-intensity field strengths and cause minimal electrolysis. The chambers may operate batchwise or continuously. The earliest versions operated batchwise. They were not fully enclosed and so were limited to a field strength of about 25 kV cm^{-1} because this was the approximate breakdown voltage of air.[25,107] Enclosure and design improvements led to batchwise devices that could deliver 30 to 40 kV cm^{-1}.[38,130] These were useful for laboratory studies to determine the optimum parameters for the inactivation of microorganisms. However, continuous operation is necessary for cost-effective industrial systems able to treat liquids or liquids containing particulates. A number of such systems, mostly designed around coaxial cylindrical electrodes, were therefore developed.[7,10,25,51,100,111,113,118]

13.3.3 Mechanism of Action

While the effects of high voltage fields on microorganisms are not understood at the molecular level, the gross effects, and the mechanisms that cause them, are well established. They result from permeabilization of the cell membrane.[41] Microbial cells act as insulators due to the low conductivities of their membranes so that, at low field strengths, they resist the effects of electric pulses. The field is effectively excluded from the microbial cell. As the field strength is raised, however, it becomes sufficient to overcome the resistance of the membrane in such a way that the voltage gradient across the whole cell is concentrated across the membrane at the two ends of the cell that are perpendicular with respect to the field gradient (Figure 13-5). It has been established that breakdown results when the voltage drop across the membrane reaches about 1 volt.[15,35] Although this may seem small, the fact that the membrane is only a few tens of Ångstroms across, results in the development of an enormous voltage gradient across it. It will be clear from Figure 13-5 that large cells (eg, yeasts) will therefore be expected to be killed at lower field strengths than small cells (eg, micrococci) and, indeed, this has been found to be so.[41]

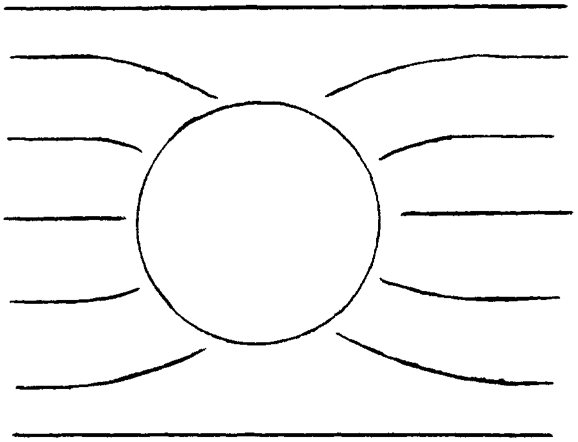

Figure 13-5 Diagrammatic Representation of the Influence of the Cell Membrane on the Equi-Potential Lines during High Voltage Discharge Treatment. The arrow indicates the direction of the applied field. *Source:* Reprinted with permission from A.J.H. Sale and W.A. Hamilton, Effects of High Electric Fields on Microorganisms II: Lysis of Erythrocytes and Protoplasts, *Biochimica et Biophysica Acta,* Vol. 163, pp. 37–45, © 1968, Elsevier Applied Science.

The result of the membrane damage is to make the cell temporarily leaky. It may survive if the damage is not extreme; this is the basis of electroporation. At higher voltages massive leakage of cell contents occurs and the cell dies.[124]

13.3.4 Effects on Microorganisms

Vegetative cells of bacteria, yeasts, and molds are inactivated by sufficiently high electric field pulses as a direct result of membrane permeabilization. Pulsed-field inactivation has been reported for *E. coli, S. typhimurium, S. dublin, Streptococcus thermophilus, Lactobacillus brevis, Pseudomonas fragi, Klebsiella pneumoniae, S. aureus, L. monocytogenes, S. cerevisiae,* and *Candida albicans.*[5] In contrast to vegetative organisms, bacterial spores[107] and yeast ascospores[78] were resistant, even at voltage gradients above 30 kV cm^{-1}, though recently the first reports of spore inactivation have been made.[76] The effect of increasing voltage gradients is illustrated in Figure 13-6 for a number of bacteria and yeasts. The data show the large differences in the resistance of different microorganisms and illustrate the general observation that large-celled species are more sensitive than small-celled ones.

With respect to the inactivation of microorganisms in foods, a number of controllable intrinsic and extrinsic factors influence the effectiveness of electrical treatments. Inactivation increased greatly with increase in temperature, eg, for *E. coli* between 3° and 40°C (Table 13-1).[100] Similar data were reported for *Lactobacillus brevis*[62] over the range 24° to 60°C, but with the probability of some thermal inactivation at the higher end of the temperature range. Low ionic strength favors inactivation by pulsed electric fields such that a reduction in the KCl concentration in simulated skim milk from 0.17 to 0.03 M resulted in a fall in the surviving fraction of *E. coli* following a 55 kV cm^{-1}, 20 pulse treatment, from about 0.3 to 0.002.[125] Reduction in pH value increased inactivation, eg, it was approximately doubled for *E. coli* when the pH of skim milk was reduced from 6.8 to 5.7.[125] Log-phase cells are more sensitive than stationary-phase cells.[125] Application of electric treatments to liquid foods has indicated that useful *cold pasteurization* inactivation of yeasts and vegetative microorganisms can be achieved. For example, treatment of apple juice, at temperatures below 30°C, with less than 10 pulses in a continuous treatment chamber, caused >6 log reduction of *Saccharomyces cerevisiae* at voltage gradients of 35 kV cm^{-1}; 22 kV cm^{-1} delivered just over 2 log inactivation.[98]

Table 13-1 Effect of Temperature on the Inactivation of *Escherichia coli* by High Voltage Electric Discharge Treatment (50 kV cm^{-1}, 2 μsec pulses) in Simulated Skim Milk

	Surviving Fraction after Total Treatment Times (microsec) of

There is a problem in the commercial use of high voltage pulse technology that results from the kinetics of inactivation. Studies of inactivation rates under a variety of conditions have generally indicated kinetics that, on a log survivor versus treatment time, or versus number of pulses basis, show long "tails." Near straight lines are seen when log survivors are plotted against the log of the treatment time, or against the log of the number of pulses (Figure 13-7).[131] This means that whereas a small number of pulses may satisfactorily treat a food if a small number of log reductions in the target organism is required, the number of pulses needed increases greatly if high log reductions are required. For example, from Figure 13-7, *E. coli* would be about 10^3-

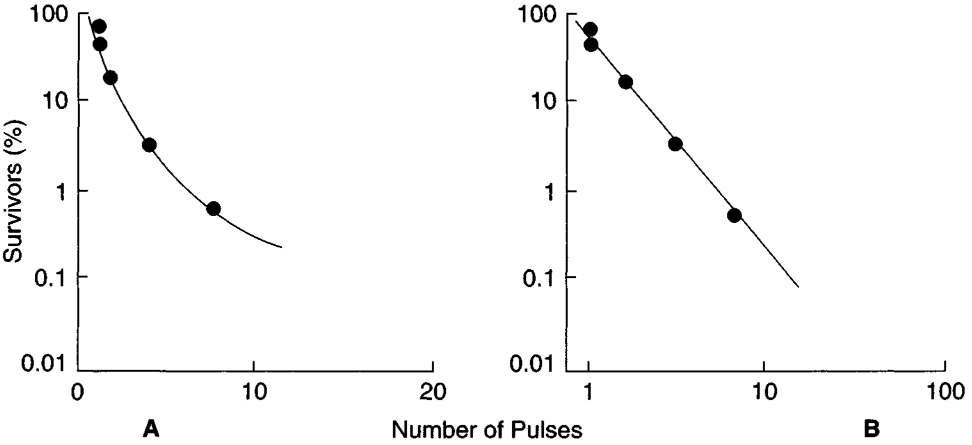

Figure 13-7 Inactivation Kinetics of *Escherichia coli* in Simulated Milk Ultra-Filtrate at 20°C by 35 kV cm^{-1}, 2 microsec Pulses. (**A**) Log survivor:linear dose plot. (**B**) Log survivor:log dose plot. *Source:* Adapted with permission from Q. Zhang et al., Inactivation of *E. coli* for Food Pasteurization by High-Strength Pulsed Electric Fields, *Journal of Food Processing and Preservation,* Vol. 19, pp. 103–118, © 1995, Food and Nutrition Press, Inc.

fold inactivated by 10 pulses under the conditions indicated but (extrapolating) more than 100 pulses would be required to achieve a 10^6-fold inactivation, and more than 1,000 to achieve a 10^9-fold kill. Nevertheless, at higher field strengths (eg, 70 kV cm^{-1}) 10^9-fold kills can be achieved with 100 pulses (*E. coli* at 20°C). This is judged to be an economically feasible basis for commercial cold pasteurization of pumpable liquid foods, with the advantages of minimal changes in flavor, color, and texture.[131,132]

While most research into the effects of electric pulses on microoganisms has involved single treatments, studies of combination processes have shown potentially useful synergies. For example, electroporated cells of *L. monocytogenes, E. coli,* and *S. typhimurium* become much more sensitive than untreated cells to nisin and pediocin.[64]

13.4 HIGH-INTENSITY LIGHT

High-intensity laser or noncoherent light has long been known to be capable of inactivating microorganisms,[78] though it is often unclear to what extent the effects seen result from the ultraviolet component of the irradiation and, sometimes, local transient heating. Low power ruby lasers were shown to inactivate vegetative bacteria more than 30 years ago[66] and later studies demonstrated the killing effects of laser light at wavelengths from 193 nm in the ultraviolet to 10,600 nm in the infrared.[1,31,97,128]

A number of studies explored the use of lasers to inactivate microorganisms in the medical area, particularly dentistry.[19,97,103] The delivery of light to equipment surfaces, packaging material, food product surfaces, and transparent liquid foods, in short duration high-intensity pulses, has been described and shown capable of inactivating vegetative and spore forms of microorganisms in these environments.[24] The numbers of *E. coli* in biofilms adhering to stainless steel surfaces were reduced more than 10^3-fold by a single 20 nsec pulse of laser light delivered at less than 50 MW (Megawatts) cm^{-2}. Energy densities up to 600 MW cm^{-2} resulted in more than 10^6-fold reductions.[104] It was shown that the biofilmed surface was decontaminated primarily by physical removal ("ablation") rather than by thermal or photochemical inactivation of the bacteria. Efficiency was, therefore, increased when the aerosolized organisms released by the process were drawn off to minimize redeposition. The process was more effective than most commonly used chemical treatments, which generally deliver 2- to 3-log inactivation of vegetative bacteria in biofilms on a variety of materials, including stainless steel.[8,52] While safety and technical constraints may limit the widespread use of pulsed lasers for equipment surface decontamination in the near future, dedicated uses, such as fixed in-line components of equipment requiring decontamination at critical points, are more likely, for example, to decontaminate rotating blades in cooked meat slicing processes.[104]

Surface treatments with 1,064 nm light at an output pulse energy of about 10 J delivered over 8 msec at a pulse repetition rate of 10 Hz inactivated a variety of Gram-negative and Gram-positive bacteria (*E. coli, Serratia marcescens, S. aureus, B. subtilis, B.*

stearothermophilus, Micrococcus luteus, Deinococcus radiodurans) and yeasts (*S. cerevisiae, C. albicans*). Using a rough endpoint method of assessment (growth/no growth from initial numbers of probably 10^6 or so), *C. albicans* was the most sensitive, inactivated by 1,388 J cm^{-2}; *E. coli* and *M. luteus* were of intermediate resistance (2,020 and 3,130 J cm^{-2}, respectively) and vegetative cells of *B. stearothermophilus* were most resistant (4,371 J cm^{-2}). Total treatment times were in the order of 20 seconds.[126]

Commercially practical machines for treating foods with high-intensity noncoherent light pulses, coupled with aseptic packaging, have been patented.[24] These machines use broad spectrum light with pulse durations from 10^{-6} to 10^{-1} second and with energy densities from 0.1 to 50 J cm^{-2}. Different spectral distributions and energies are selected to match the requirements of different applications. For example, ultraviolet-rich light in which about 30% of the energy is at wavelengths shorter than 300 nm is recommended for treatment of packaging materials, water, or other transparent fluids. The killing effects in this case mainly derive from the ultraviolet component of the absorbed light. In contrast, for the treatment of food surfaces, particularly when ultraviolet irradiation may cause undesirable changes in the product, such as acceleration of lipid oxidation or color bleaching, the ultraviolet is filtered out. The killing effects are then largely thermal. The advantage of delivering heat in this manner is that a large amount of thermal energy is transferred to a very thin layer of the food surface very quickly. Consequently, the temperature rise in the interior of the food is very small.[24] The efficacy of the machines have been demonstrated against vegetative cells (*E. coli, S. aureus*), yeast (*S. cerevisiae*), and spores of bacteria (*B. subtilis*) and fungi (*Aspergillus niger*). The contribution of the ultraviolet component was illustrated by the much reduced killing effect of ultraviolet-filtered light. While one pulse of 12 J cm^{-2} unfiltered light inactivated vegetative cells of *B. subtilis* by about 6 logs, as many as 15 pulses of ultraviolet-filtered light only reduced numbers by about 0.5 log, and 25 pulses by about 3.5 log.[24]

Overall, therefore, these intense light treatments are effective mainly because they deliver conventional inactivating treatments, ultraviolet irradiation or heat, but in an unconventional manner that may be advantageous in some circumstances.[78]

13.5 HIGH-INTENSITY MAGNETIC FIELDS

Exposure to oscillating magnetic fields has been claimed to have a variety of effects on biological systems ranging from selective inactivation of malignant cells with relatively little damage to normal tissues[20] to the inactivation of bacteria on packaging materials and in foods.[50] The antimicrobial procedures involve exposing the target materials to pulses of very high magnetic intensity, at magnetic fluxes from 2 to about 100 tesla, at frequencies between 5 and 500 kHz. Total treatment time is very short, typically from 25 µsec to a few msec.

The mechanism of action is not known. Temperature rise during magnetic pulse treatments was not more than 5°C, and usually about 2°C. It has been suggested that the magnetic energy couples into dipolar molecules and may change membrane fluidity and alter ion fluxes across cell membranes.[96] No inactivation of bacterial spores has been reported. Efficacies of the treatments did not exceed about 100-fold reductions in numbers of vegetative microorganisms inoculated into milk (*Streptococcus thermophilis*), orange juice (*Saccharomyces*), and bread rolls (unspecified mold spores),[50] therefore, the practical applications for the technique appear to be limited.[5,78]

13.6 MANOTHERMOSONICATION

The use of ultrasound to accelerate chemical reactions and to inactivate microorganisms was first proposed 70 years ago.[42] Since then, ultrasound has been employed widely in *sonochemistry,* for cleaning and for dispersing, homogenizing, and emulsifying liquids, and has been promoted for speeding up age-related changes in foods such as meat and wine.[105]

The mechanism of action of ultrasound derives from the rapidly alternating compression and decompression zones propagating into the material being treated and the cavitation that these cause. Cavitation involves the formation and collapse of small bubbles, generating shock waves of very high local pressure and temperature that can be sufficiently intense to catalyze chemical reactions and to disrupt animal, plant, and microbial cells.[112] Generally, large cells are more susceptible than small ones.[2] Cocci are more resistant than rod-shaped bacteria[3] and Gram-positive more sensitive than Gram-negative bacteria,[2] while spores are so much more resistant as to be essentially nondisruptable.[109]

Early work on the biocidal effects of ultrasound was usually carried out with temperature control designed to rule out any effects due to heat. It was not until 1972 that deliberate determination of the combined effects of ultrasound and heat showed that a potentially useful synergy occurred, even with the normally ultrasound-resistant spores of *B. cereus* and *B. licheniformis*,[9] as well as with thermoduric streptococci,[87] *S. aureus*, and other vegetative microorganisms.[86] Further work confirmed the heat-ultrasound synergism, but also showed that as the temperature was raised the potentiating effect of ultrasound became less and less, disappearing at the boiling point of the menstruum, ie, near to 100°C for most foods.[33] The important discovery that led to the development of manothermosonication (MTS) was that this disappearance of the synergism could be prevented by raising the pressure.[105] MTS therefore involves simultaneously heating and ultrasonicating foods while under a small overpressure, commonly no more than 1 MPa (about 10 atmospheres). The process generally has the effect of reducing the apparent heat resistance of microorganisms by about 5° to 20°C or, on a kinetic basis, by between 6- and 30-fold depending on the temperature, the organism, and its *z*-value. Yeasts are more sensitive than bacteria to the additional effects of ultrasonication. Figure 13-8 illustrates the magnitude of the effects of MTS on spores. While the MTS process has not yet been commercialized, it has been shown to operate in liquid foods (eg, milk[105]), offering the possibility of new sterilization or pasteurization processes for this and other liquid foods, such as fruit juices, sauces, and dressings, with reduced levels of thermal damage. It is less likely that the process would be of value for solid foods or foods containing other than very small particulates because of the absorption of the ultrasonic energy that would be expected to occur.

13.7 CONCLUDING REMARKS

The use of physical techniques to inactivate microorganisms in foods without the application of heat, or with the delivery of less heat than would otherwise be necessary, is attractive from the point of view of food product quality. The techniques surveyed above all aim to achieve this. However, four principal factors limit their usefulness at present.

The first is that bacterial spores remain the organisms most resistant to all the new techniques, so that their use for the sterilization of low acid–high a_w foods for long ambient stability is not possible, with the possible exception of MTS. Consequently, the techniques are limited to pasteurization-like processes for foods in which spores are not a problem (eg, jams and fruit juices) or which have a limited chill shelf life. Effective control of spores by combining the new techniques with other preservation adjuncts has already been proposed (eg, pressure plus heat, pressure and electric pulse treatments plus bacteriocins, the MTS treatment itself) and may offer a way forward, but the commercial feasibility of such approaches remains to be established.

The second important factor is that, should such combination treatments be pursued, then their safety implications require much more consideration. For example, in the use of alternative methods for the commercial sterilization of low acid–high a_w foods (eg, low-acid canned foods) the same safety factor that is used in heat processing, ie, a 12-decimal reduction of viable spores of *C. botulinum*, would be needed. How-

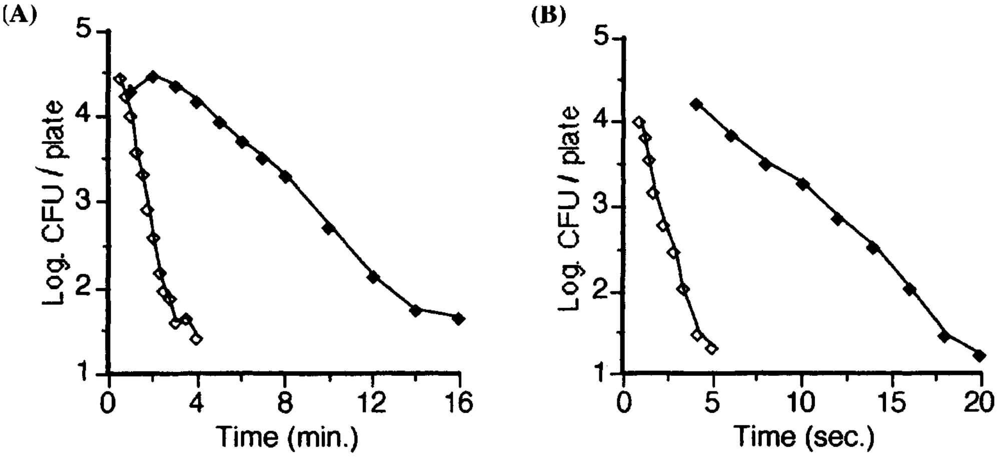

Figure 13-8 Synergism of Heat with Ultrasound (20 kHz, 117 μm) under Pressure (300 KPa) in the Inactivation of Spores of *Bacillus subtilis*. MTS-treated (◇) and heated controls (◆). **(A)** 100°C. **(B)** 112°C. *Source:* Reprinted from F.J. Sala et al., Effect of Heat and Ultrasound on Microorganisms and Enzymes, in *New Methods of Food Preservation,* G.W. Gould, ed., pp. 176–204, © 1995, Aspen Publishers, Inc.

ever, spores of some strains of *C. perfringens, B. cereus, B. subtilis,* or *B. licheniformis* may show greater resistance (relative to that of *C. botulinum* spores) to alternative processes than to heat and may therefore contribute to a need for a more severe treatment than dictated by *C. botulinum* spores. In the development of heat pasteurization processes the main pathogens against which the processes were targeted were (1) for pasteurization of milk, *Mycobacterium* and *Brucella* species and *Coxiella burnetii* (2) for liquid egg, *Salmonella* species (3) for "Sous Vide" and similar foods, vegetative pathogens, and spores of nonproteolytic *C. botulinum.* New methods of pasteurization should be designed to give at least an equivalent safety factor to that delivered by heat processing against these organisms. In addition, it should be recognized that other vegetative pathogens may show a higher degree of resistance to the alternative methods of processing than do the organisms mentioned above; for example, *L. monocytogenes* and verotoxin-producing *E. coli* (in particular *E. coli* O157) may need particular consideration. It would be necessary to select the relevant pathogen that showed the highest resistance to the proposed type of treatment and to specify that the extent of treatment given should reduce its viable numbers by an agreed factor, eg, 10^4, 10^5, or 10^6.

Third, the kinetics of microbial inactivation by some of the techniques is evidently far from the exponential relationship that, even with the deviations sometimes known to occur, has become the basis of sound thermal processing. It may be difficult to accommodate unusual kinetics, eg, into sensible risk analyses for the new processes.

Fourth, although an advantage of the most successful of the new processes, isostatic pressure, is that it treats all parts of a food equally, the efficacy of most of the other techniques is impaired by food structure. In particular, high-intensity light is limited to relatively transparent foods or surfaces, electric pulses and MTS will probably be limited to liquid foods or foods with small particulates.

However, while it is important to be clear about the possible problems, there clearly are opportunities for the use of some of the new techniques and, particularly if new combination approaches are developed and proven to be effective, these opportunities are likely to expand in the future.[4]

14.1 INTRODUCTION

The preservation of almost all foods in industrialized and developing countries is based on combinations of several preservative factors that secure microbial safety, stability, and the sensory quality of these foods. This is true not only for traditional foods, but also for novel products. The most important preservative factors (also called hurdles) in common use for food preservation are high temperature (F value), low temperature (t value), water activity (a_w), acidity (pH), redox potential (Eh), some preservatives, and the competitive flora.[42] However, more than 50 factors (hurdles) of potential use for improving the stability and quality of foods have been described,[12] and the list of possible hurdles for the preservation of foods is by no means complete.

The factors used in combination for the preservation of foods might have additive or even synergistic effects on each other. The complex interactions of preservative factors present in foods is illustrated by the so-called hurdle effect,[34,42] which indicates that a food is stable and safe if the hurdles in this food cannot be overcome by the microorganisms present. From an understanding of the hurdle effect, hurdle technology has been derived,[36] which allows improvements in the microbial stability and sensory quality of foods by deliberate and intentional combinations of hurdles. Over the years, the insight into the hurdle effect has been broadened and the application of hurdle technology extended. In industrialized countries, the hurdle technology concept is currently of particular interest for minimally processed, fresh-like foods. In developing countries the application of hurdle technology is most attractive for the preservation of foods that are stable and safe without refrigeration.

The application of hurdle technology is advancing rapidly worldwide. This concept is synonymously called Hürden-Technologie in German, hurdle technology in English, technologie des barrières in French, barjernaja technologija in Russian, tecnologia degli ostacoli in Italian, tecnologia de obstaculos in Spanish, shogai gijutsu in Japanese, zang lan gi shu in Chinese, etc.[48] However, it should be noted that the hurdle effect has been used empirically since ancient times. It was used for the mummification of the Egyptian pharaohs as an old example of "tissue preservation" based on the hurdle effect. Mummies contain at least three hurdles, namely reduced a_w (0.72), increased pH (10.6), and preservatives (spices, aromatic plants), as has been demonstrated by Chirife et al.[16] However, only recently has increased understanding of the principles behind the hurdle effect made it feasible to begin to replace empirical processes by an intentional and intelligent selection of hurdles for the preservation of foods by the application of hurdle technology.

This chapter will concentrate on foods of developing countries. First, the principles of food preservation procedures used in developing countries will be discussed. Secondly, some recent developments in food preservation based on hurdle technology in different regions of the world will be outlined, by discussing examples from Latin America, China, India, and Africa.

14.2 PRINCIPLES OF FOOD PRESERVATION IN DEVELOPING COUNTRIES

There exists an abundant variety of preserved foods in developing countries because the gap between harvest peaks has to be bridged, and the taste and nutritional properties of foods might improve because of preservation. The processes employed for the preservation of foods in developing countries are largely based on the same principles as in industrialized countries, such as heating, chilling, freezing, drying, salting, sugar addition, acidification, fermentation, oxygen removal, and addition of preservatives.

However, the emphasis differs considerably. Whereas in industrialized countries, low temperatures (chilling, freezing) are widely used for the preservation of food, the required energy for these processes is costly in many developing countries and not reliably available. Canning and autoclaving, ie, the application of high temperatures, are also less suitable for developing countries because they require large investments and much energy. On the other hand, reduced water activity (a_w) is a suitable and prevalent procedure for food preservation in developing countries. Methods of drying and/or addition of salt or sugar to foodstuffs are often combined with a reduced pH (increased acidification). Fermentation of foods also is a traditional and common preservation process in developing countries. If lactic acid bacteria are used for fermentation, acidification (low pH) contributes to the preservation of foods. If molds are employed, in addition or separately, the taste and the nutritional properties of foods during fermentation improves. The variety of fermented foods is larger in developing than in industrialized countries, and the types of products differ considerably by the regions. Oxygen removal by vacuum packaging is already quite widespread in developing countries, an older process with a similar purpose is to cover foods with a layer of oil. Preservatives are occasionally added in excessive amounts to foods by artisans in developing countries, but in some regions, such as some parts of Africa, they might be too expensive and therefore "natural preservatives," like spices or herbs and their extracts, are preferred. For other reasons industrialized countries prefer to avoid chemical preservatives, and also prefer conventional or unconventional natural preservatives.

It may be concluded that reduction of the water activity is the principal preservative factor in developing countries, and that intermediate-moisture foods (IMF) with an a_w range of 0.90 to 0.60 are the prevalent food items. However, practically none of the food manufacturers in developing countries has the possibility to measure a_w, and few even recognize the relevance and significance of the water activity for the preservation of their foods.

Within the framework of the CYTED-D program (Science and Technology for Development, Fifth Centennial), which was sponsored by Spain and to which Argentina, Brazil, Chile, Costa Rica, Cuba, Mexico, Nicaragua, Puerto Rico, Uruguay, and Venezuela have contributed, two projects were carried out from 1986 to 1994.[77] The first project, entitled "Development of Intermediate Moisture Foods (IMF) Important to Ibero-America" had the objectives of identifying and evaluating foods of Latin America that are storable without refrigeration. The foods comprised fruits, vegetables, and bakery products as well as foods derived from fish, milk, meat, and miscellaneous products. About 260 food items were approved to be microbiologically stable and safe without refrigeration. The properties (a_w, pH, preservatives, food composition, etc) and the production technology for these products were described.[1,76] It was concluded that most of the approved products were intermediate-moisture foods. However, some had high a_w values and nevertheless were stable and safe without refrigeration, and it turned out that the stability of these high-moisture foods was caused by a combination of several empirically applied hurdles. This observation was the starting point for Latin American researchers to apply intentional hurdle technology[36] to high-moisture foods, especially fruits, storable without refrigeration. Therefore, the second project within the framework of the CYTED-D program, with national financial contributions from the participating countries, was entitled "Bulk Preservation of Fruits by Combined Methods." The main objective of this project was to develop simple and inexpensive processes that would help to diversify the Latin American fruit industry and to reduce the large post-harvest fruit losses.[77] These two projects of the CYTED-D program resulted in an impressive number of refereed papers, contributions to food congresses, and B.S. and graduate theses.

The Latin American CYTED-D study demonstrated a promising approach for improving the stability of foods in developing countries, which could also be applied in other regions. Following this concept, first the properties of already available, microbiologically stable and safe food items should be thoroughly studied and described. Second, the preservation factors (hurdles) effective in these foods, and thus the principles behind their microbial stability and safety, must be elucidated. Third, if feasible, the preservation and quality of these foods should be improved by the intentional application of hurdle technology.

Using this concept, Tapia de Daza et al.[64] have identified the hurdles in the food items studied within the first project of the CYTED-D program, and by critical evaluation of the hurdles that have been traditionally applied to certain foods, they assessed the products' microbial stability and safety. It was demonstrated that similar hurdles are active in the same type of foods in different Latin American countries. However, there were also surprising differences, which pointed to an over- or underprocessing of the same food in different countries of the same region. This insight could lead to the avoidance of some nonessential preservatives or, on the other hand, to an improved stability, safety, and quality of some food items by fortification of certain hurdles.

In the following sections, the principles on which the preservation of intermediate-moisture and high-moisture foods in developing countries are based will be discussed in relation to the preservative factors (hurdles) applied.

14.2.1 Intermediate-Moisture Foods

Latin American researchers[64,76] pointed out that reduced water activity was the main hurdle in the intermediate-moisture foods (IMF) they described within the first CYTED-D project. However, in practically all of these products, additional hurdles were present that contributed considerably to stability and safety. Thus, the microbial stability of most of these IMF was based on a combination of preservation factors. This observation confirmed the opinion expressed by Leistner and Rödel[33] that in most intermediate-moisture foods several hurdles are inherent.

A case in point is pastirma, a typical IMF of developing countries. Pastirma is a traditional beef product of Moslem countries. It is storable for several months at ambient temperatures and is eaten in the raw state.[19] The stability and safety of pastirma is based on the reduced a_w (0.90–0.85), in combination with several additional preservative factors.[38] The interior of this product is stabilized by the addition of salt and nitrate (which is reduced by bacteria to nitrite) and the removal of water by drying and pressing of the meat, as well as by the growth of lactic acid bacteria, which decreases the pH to about 5.5. These hurdles secure the inhibition of spoilage and pathogenic bacteria, including salmonellae, within the meat. The surface of pastirma is covered with an edible paste containing 35% freshly ground garlic and other spices (paprika, kammon, mustard with fenugreek as a binder). This surface coating prevents the growth of molds on the product during storage, even at higher humidities and temperatures. Therefore, at least five hurdles (a_w, nitrite, pH, competitive flora, garlic) are relevant to the preservation of pastirma. Guidelines suggested for safe processing of traditional pastirma (Exhibit 14-1) shall secure that the hurdles inherent to this product are effective.[38]

Tapia de Daza et al.[64] listed many traditional IMF of Latin America, derived from fruits, vegetables, meat, milk, fish, etc, in which several identified

Exhibit 14-1 Guidelines for Processing of Traditional Pastirma, a Raw Meat Product of Moslem Countries

1. Lean meat from the hindquarter of healthy beef cattle should be used (this secures low initial bacterial counts).
2. Meat should be cut into strips of not more than 5 cm in diameter (allows a quick penetration and equilibration of salt).
3. The a_w of the meat must be decreased quickly by addition of sufficient salt and by pressing the meat to reduce moisture (the salt content of the finished product should be 4.5% to 6.0% and the a_w 0.90–0.85).
4. With the salt about 600 ppm nitrate is added to the meat (which after reduction to nitrite inhibits undesirable bacteria, especially at reduced pH).
5. Growth of lactic acid bacteria (up to 10^7/g) in the paste and in the meat is desirable as competitive flora and for pH reduction (but for sensory reasons the pH should not be <5.5).
6. After drying, the meat must be covered with a paste containing several spices and 35% freshly ground garlic (the spices and especially the garlic inhibit salmonellae in the meat as well as mold growth on the surface of the product).

hurdles contributed to microbial stability and safety. Very often the reduced a_w was combined with a reduced pH. However, in some salted fish and shrimps, the pH was >8.0, and thus in these foods the elevated pH might contribute to preservation. Many meat, fish, fruit, and dairy products contained additional preservatives (eg, nitrite, smoke, benzoate, sorbate, sulfites, spices, and Maillard products) and sometimes competitive microorganisms. Maillard reaction products, which are generated during the desired caramelization of sweet condensed milk (dulce de leche), are probably an important hurdle for this Latin American food item.

A special case concerns candied fruits common in this region. Their heavy sugar coating acts as a physical barrier (hurdle) against microbial contamination after the heat process, so that these foods are stable during storage in spite of the absence of preservatives and a sometimes rather high pH. Quite often a thermal treatment is used to inactivate heat-sensitive microorganisms during the manufacturing process and to improve microbial stability, and a vacuum in sealed containers is achieved by hot filling of the products. Once the container is opened, the redox potential increases and then the microbial stability of these IMF against molds and yeasts must be secured by the preservatives present. Additional hurdles are employed in particular in those IMF which have rather high a_w and/or pH values. In the IMF studied, it was exceptional if the low a_w was apparently the only hurdle present. This was likely in a dried Brazilian meat product as well as in traditional salted fish with an a_w close to 0.75. However, in most IMF products, three to five hurdles have been identified.[64]

How many hurdles, besides the a_w, are active in intermediate-moisture foods depends on the type of the product; however, it may be concluded that the microbial stability and safety of IMF in general is based on a combination of several preservative factors.

14.2.2 High-Moisture Foods

Many food products with a water activity above 0.90 need refrigeration during storage, and therefore are less suitable for developing countries. For example, cooked ham with much water added (a_w close to 0.99) was introduced to China, but such products easily spoil or even cause food poisoning if not adequately chilled. Therefore, developing countries should be cautious when introducing high-moisture foods from industrialized countries.

However, there are Western meat products available that, in spite of a rather high water activity (a_w 0.97–0.92), are microbiologically stable and safe without refrigeration because they have been stabilized by the application of intentional hurdle technology.[44,48] The same holds true for other food items that are indigenous to developing countries,[1,64,76] even though their effective preservative factors (hurdles) have only been partially identified.

There is a trend in developing countries to move gradually away from intermediate-moisture foods because IMF are often too salty or too sweet, and have a less appealing texture and appearance than high-moisture foods (HMF). High-moisture fruit products (HMFP) were studied in the second project of the CYTED-D program.[77] It might be expected that high-moisture, fresh-like foods, which are storable without refrigeration because they are stabilized by combined preservative factors, will be generally on the increase in developing countries as soon as the application of hurdle technology has been mastered. Such products are minimally processed, convenience foods, now the trend in industrialized as well as in developing countries. These foods are often refrigerated in industrialized countries; however, in developing countries they should remain stable, safe, and even fresh-like if stored for an extended time at ambient temperatures.[66,67] The independence from the chill chain renders high-moisture, convenience foods, such as HMFP, much more suitable for developing countries.[6]

14.3 RECENT APPLICATIONS OF HURDLE TECHNOLOGY IN DEVELOPING COUNTRIES

Food preservation in developing countries has a time-honored tradition and a wealth of products are known which deserve respect.[40] Nevertheless, improvements in microbial stability, safety, and sensory quality of these foods are feasible. Researchers in developing countries are working in this direction by taking recent accomplishments in food science and technology into consideration. One of these developments is the knowledge about food preservation based on an understanding of the hurdle effect and the application of hurdle technology. This knowledge emerged from the German Meat Research Institute and a number of relevant publications[33,35,36,38,42,44,45,48,49,50] were utilized by food scientists worldwide. In addition, the author of this chapter was invited in recent years to present numerous lectures and courses in more than 20 developing countries.

Presently, several groups of researchers are working worldwide on the improvement of traditional foods as well as the development of novel products, by taking the hurdle effect and hurdle technology into account. Some examples of recent results obtained in Latin America, China, India, and Africa will be discussed.

14.3.1 Latin America

Fruits

In general, fruits are an important and abundant commodity in developing countries; therefore, Latin American researchers have concentrated on improvements in the preservation of tropical and subtropical fruits. They first concluded from their studies that intermediate-moisture fruits (IMF) are more attractive for consumers than fully dried products.[76] However, the high solute concentration necessary to depress the water activity of IMF often causes undesirable alterations of the product flavor. Therefore their second conclusion was that intermediate-moisture fruits do not seem to be a good option for tropical and subtropical fruit marketing.[77] Jayaraman from India agreed with these conclusions in a recent review paper, and pointed out that intermediate-moisture fruits face technological problems and consumer health concerns associated with the high levels of humectants and preservatives required for their shelf stability.[30,31]

Therefore, work was launched in Latin America to preserve fruits as high-moisture foods (HMF) by using combined preservative factors (hurdle technology). Objectives of this approach were to develop simple, inexpensive, energy efficient processes for the local fruit industry, which could overcome seasonal production constraints and reduce post-harvest losses (Exhibit 14-2). The main goal was to preserve fruits in fresh-like condition even if stored for several months without refrigeration.[66,67] The first success in this endeavor was reported with preservation of peaches.[62] By using a similar approach, an excellent microbial stability and fresh-like quality was achieved with pineapple[3] as well as with banana, chicozapote, mango, and papaya,[4] and in an independent study again with papaya.[53] Additional investigations added figs, passion fruit, plum, pomalaca, strawberry, and tamarind to the list of fruits preserved as high-moisture products.[5] The fruits were preserved whole, sliced, or as purees. For some fruits, the process was scaled up to a pilot plant–size operation. However, the introduction of these processes to real industrial production has not yet been achieved.[67]

Exhibit 14-2 Objectives for Preservation of Fruits in Bulk by Combined Methods in Latin America

To develop technologies that should:
—be simple and inexpensive
—be energy efficient (independent of chill chain)
—be suitable for processing at production sites
—help overcome seasonal production constraints
—contribute to diversification of local fruit industries
—help to reduce post-harvest losses
—preserve fresh-like properties of raw materials

Within the CYTED-D program, seven Latin American countries contributed to this exercise, and outstanding contributions came from Argentina (Departamento de Industrias, Universidad de Buenos Aires, Buenos Aires), Mexico (Departamento de Ingeniería Química y de Alimentos, Universidad de las Américas-Puebla, Puebla), and Venezuela (Instituto de Ciencia y Tecnología de Alimentos, Universidad Central de Venezuela, Caracas).

Alzamora et al.[3,4] have suggested five hurdles for the preservation of high-moisture fruit products (HMFP): (1) mild heat treatment (to inactivate enzymes and to lower the initial microbial load), (2) slight reduction of a_w (by addition of sucrose or glucose), (3) pH adjustment if necessary (by addition of citric or phosphoric acid to fruits with higher pH), and (4) and (5) the addition of two preservatives (potassium sorbate or sodium benzoate and sodium sulfite or sodium bisulfite) in moderate amounts (Table 14-1).

The process is quite simple to carry out (Figure 14-1) and, therefore, could be established at harvesting

Table 14-1 Typical Process Used for the Preservation of High-Moisture Fruit Products (HMFP)

Hurdles	*Intensity*
1. Heat treatment*	Saturated steam for 1–3 minutes
2. Water activity†	a_w reduction to 0.98–0.94
3. Acidification‡	pH adjustment to 3.0–4.1
4. Preservative (I)	1,000 ppm sorbate or benzoate
5. Preservative (II)	150 ppm sulfite or bisulfite

*Dependent on size and type of fruit.
†Adjusted with sucrose, glucose, maltodextrins, etc.
‡Adjusted with phosphoric or citric acid.

Raw fruit
Selection, washing, peeling and cutting
Blanching
1–2 minutes in saturated steam and cooling in running water
Equilibration
a_w = 0.94–0.98
pH = 3.0–4.1
PS = 1,000–1,500 ppm
SO_2 = 150 ppm
Addition of sugar syrup, phosphoric/citric acid, potassium sorbate (PS), and sulfur dioxide (SO_2)
Reuse of syrup
Packaging
In glass or plastic pouches, with enough syrup to cover all the fruit pieces

Figure 14-1 Flow Diagram for the Production of Shelf-Stable HMFP (Mango, Papaya, Peach, Pineapple, etc). *Source:* Adapted with permission from M.S. Tapia de Daza, S.M. Alzamora, and J. Welti Chanes, Combination of Preservation Factors Applied to Minimal Processing of Foods, *Critical Reviews in Food Science and Nutrition,* Vol. 36, pp. 629–659, © 1996, CRC Press, Inc.

places. It results in stable and safe fresh-like products storable for at least 3 to 8 months (ie, from one harvest peak to the next) at ambient temperatures by using modest packaging.[3,4,7,53] Even after this long storage at 25°–35°C, sometimes in bulk, the taste, flavor, color, and texture as well as the overall acceptability were rated by untrained panels (30 to 50 members) quite high,[4,5,53] as shown in Table 14-2. This is especially noteworthy for the texture, which often is not satisfactory after canning or freezing of fruits. The main characteristics lost and, therefore, the ones that determine the sensory shelf life of HMFP are color and flavor.[7] The average scores of HMFP have always corresponded to products with good acceptability, which leads to the conclusion that such products can be regarded as attractive alternatives to conventional fruit preservation methods.[4,7,53,66,67] Preserved HMFP can be eaten as they are or may be used for out-of-season processing in confectionery, bakery goods, dairy products, jams, jellies, etc. Fruit pieces can also be utilized as ingredients in salads, barbecues, pizza, yogurt, and fruit drink formulations.[5,7] Because HMFP can help to reduce post-harvest losses and serve as a supply regulator, they may lead to important economical and social impacts.[7]

The effective preservative factors listed in Table 14-3 have proven suitable to secure the microbial stability and sensory quality of HMFP. However, these hurdles should not be regarded as inflexible, and if other combinations of preservative factors become known that are even more suitable for the stability and quality of HMFP, they should be used instead.[7,66,67] Argaiz et al. pointed out that by a modification of the types or levels of hurdles used in HMFP the sensory quality of these products could be further improved because the present hurdles were selected primarily with respect to microbial stablity.[7] For instance, a combination of citric and phosphoric acids or a total substitution of citric by

phosphoric acid in the preservation of peach by combined methods enhanced their sensory acceptability; however, this was not the case if sucrose was replaced by glucose as water activity depressor.[52] Furthermore, sulfites are effective as browning inhibitors and antimicrobials in fruits, but there are health concerns and therefore alternative browning inhibitors should be investigated.[7,55]

The preparation steps to which fresh fruits are subjected in the production process for HMFP (Figure 14-1), will have an impact on the natural flora of fruits because some procedures will decrease and others increase the microbial load. While washing may remove many of the surface organisms, the peeling, cutting or slicing might contaminate the fruit flesh. Blanching is mainly employed to inactivate enzymes in vegetables and fruits, however, it also inactivates many heat-sensitive microorganisms. Reductions in the microbial load due to blanching from 60% to 99% have been reported.[3,5,53] In addition, microorganisms that survive the heat treatment during blanching might become sensitized to other hurdles. A further decrease in viable numbers is expected to occur during the equilibrium stage in which the blanched fruit pieces or purees are exposed to the stress effects of a_w, pH, and preservatives.[65] During storage the surviving bacteria, yeasts, and mold in the syrup and the fruits of HMFP generally decrease rapidly, and the final products become practically sterile.[3,4,5,27,53,62,65] However, this occurs only if all hurdles listed in Table 14-1 are present.[27] Table 14-3 gives examples of the rapid decrease of the counts of bacteria, yeasts, and molds during storage of some HMFP, which have been studied by several groups in Latin American countries.[3,53,65] Probably the major decrease of the microbial counts in HMFP occurs already during the equilibration phase, which requires about 3 to 5 days at ambient temperatures.[66,67] However, microbiological data of this critical phase are not yet available. Because HMFP during storage become apparently sterile, pathogenic and toxigenic microorganisms are not likely to be a hazard for these foods.

Table 14-3 Microbial Counts (cfu g^{-1})* Present in Mango, Papaya, Peach, and Pineapple Preserved As HMFP and Stored for Several Months at Ambient Temperature

	Days of Storage

To observe the actual behavior of microorganisms in HMFP, it is essential to use appropriate diluents and detection or enumeration media for assessing accurately the microbiological status of hurdle technology foods.[9,10,65] The microbial stability and safety of HMFP should not only be tested by following the kinetics of the decrease of the "natural" microbial flora during processing and storage, but also by conducting challenge tests with appropriate species and numbers of microorganisms.[65] Guerrero et al.[27] performed challenge tests in a high-moisture banana puree, by using strains of *Zygosaccharomyces bailii, Z. rouxii, Saccharomyces cerevisiae, Aspergillus niger, Eurotium amstelodami, Penicillium roquefortii, Paecylomyces varioti, Bacillus coagulans, Clostridium butyricum*, and *C. pasteurianum*. The banana puree supported no growth of the organisms tested if the following hurdles were present: a_w 0.97, pH 3.4, addition of 100 ppm potassium sorbate, 400 ppm sodium bisulfite, and 250 ppm ascorbic acid.[27]

The added sorbate in the preserved HMFP degrades somewhat during storage, depending on the time and temperature of storage as well as on pH, a_w, light, presence of oxygen, packaging material, etc.[3,6,22,23,53] For instance, in peaches, pineapples, and papaya preserved by the HMFP method, sorbic acid destruction during storage amounts to about 40%.

Sulfites degrade in HMFP even faster and more completely than sorbate, depending on the type of food and the length and conditions of storage.[3,7,53,67] If the free sulfite concentration decreases too much, undesirable browning of the fruits might occur. The depletion of sorbate and sulfites during storage of HMFP is favorable in view of preservative intake by the consumer; however, it diminishes the microbial stability of the products. On the other hand, in HMFP, during storage, hydrolysis of sucrose to fructose and glucose occurs; this results in a slight decrease of the water activity of the products,[17,56] which improves the microbial stability. Generally, the interaction between applied hurdles and the food matrix must be carefully considered.[6]

Chemical preservatives, such as sorbate and sulfites, are viewed with suspicion also in developing countries, and "natural" preservatives, such as spices and herbs, are more appealing to the public. However, the addition of antimicrobial spices in effective levels is often limited by sensory impairment of the foods. This is less critical for vanillin because the taste of this major constituent of vanilla beans is compatible with the taste of various fruits.[5] It is noteworthy that vanillin used to flavor foods often originates not from vanilla beans but is a by-product of the paper industry, and thus it is not really "natural." The inhibitory effect of vanillin against yeasts[14] and molds[54] was investigated with the intention to use this "natural" preservative in HMFP. The results suggested that vanillin is of potential use for preventing yeast and mold spoilage of fruits (except those with high fat and/or protein contents, like banana and mango), if combined with a slight reduction of a_w and pH. Cerrutti et al.[15] reported that 3,000 ppm vanillin was effective to achieve microbial stability of strawberry puree, if combined with a mild heat treatment (blanching), addition of 500 ppm ascorbic acid and 1,000 ppm calcium lactate, and adjustment of a_w to 0.95 and pH to 3.0. These hurdles prevented the growth of native and inoculated spoilage flora (yeasts, molds, bacteria) for >60 days at room temperature (about 23°C).[15] However, vanillin has to be used in higher concentrations and is more expensive than the common preservatives.[54]

The fast and apparently complete disappearance of bacteria, yeasts, and molds in HMFP during processing and storage deserves particular attention. The applied blanching process (heating for 1 to 3 minutes with saturated steam) considerably reduces the microbial load of the fruits. This is an important prerequisite for the success of the following preservation steps,[5,27,65] because if fewer microorganisms are present "at the start" not so many and not so high hurdles are needed to inhibit their growth.[42] It is noteworthy that the heat treatment (blanching) in the presence of preservative hurdles would be much more effective than without them.[27] The number of bacteria, yeasts, and molds that survive the blanching (some become heat injured) and the equilibration process decreases quite rapidly within days and often below the detection limit within a few weeks of storage of the HMFP.[3,27,53,65] This surprising autosterilization of fruits preserved by the HMFP process is most likely due to *metabolic exhaustion* of the microorganisms present[47] because microorganisms that have used up their energy are not able to repair their disturbed homeostasis.[24,26] Because in the HMFP process several preservative factors (a_w, pH, sorbate, sulfite) are active, probably different targets within the microbial cells are hit at the same time, and due to this *multitarget preservation*[47] a synergistic effect of the applied hurdles is likely.[25,26] Fundamental studies about the physiological basis of the growth, survival, and death of microorganisms during food preservation are desirable, which, in the case of HMFP, for example, could underpin the observed autosterilization of the preserved foods with a better understanding of the underlying principles. In these studies, homeostasis, metabolic exhaustion, and stress reactions of microorganisms as well as the multitarget preservation of foods should be taken into account, as proposed by Gould[24,25,26] and Leistner.[47,48] The significance of stress reactions of microorganisms in hurdle technology foods, which could be compensated by multitarget preservation of these foods,[47] was recognized by Alzamora et al.[6] These Latin American researchers concluded that "less processing of foods requires more hurdles," and this definitely applies to minimally processed foods including HMFP.[6] However, these additional hurdles must certainly be compatible with the nutritional soundness and sensory quaility of minimally processed foods.

In spite of effective hurdles in HMFP, resistant microorganisms might cause spoilage problems. Of practical importance is that some yeasts develop resistance against the preservative factors acting in HMFP. *Zygosaccharomyces bailii* is especially of concern with HMFP, because this yeast might exhibit a considerable resistance to heat, low pH, reduced a_w, sorbic and benzoic acid, and sulfite.[68] It was demonstrated that an apparently resistant strain of *Z. bailii* did survive and grow in inoculated mango (a_w 0.97, pH 3.5) and papaya (a_w 0.98, pH 3.5) with an addition of 150 ppm sodium sulfite and 1,000 ppm potassium sorbate, after the sorbate level had decreased during storage of the products below about 600 ppm and the sulfite was depleted.[65] Therefore, the critical levels of preservatives for the growth of *Z. bailii* should be established and monitored during storage of HMFP.[66] Additional yeast species, such as *Z. rouxii*, *Saccharomyces acidifaciens*, and *S. bisporus* are also of concern because they might develop resistance to sorbic and benzoic acids.[9,58] *Z. bailii* and *Z. rouxii* have been recommended to be used for challenge tests conducted during the design of HMFP.[67] The probability that resistant yeasts occur in HMFP should be reduced by proper sanitary procedures and guidelines for the processing of HMFP.[66,67]

The preservation of HMFP must certainly be based on guidelines for Good Manufacturing Practice (GMP) or, if feasible and necessary, on Hazard Analysis Critical Control Point (HACCP), in order to be successful under industrial or even artisan conditions.[49] For instance, the reuse of the syrup of HMFP could become a risk in relation to a build-up of preservative-resistant spoilage yeasts, and therefore, a reuse of syrup should only be recommended after pasteurization. Furthermore, the containers used for bulk and long storage of HMFP should be covered with a lid in order to avoid a recontamination of HMFP after the added preservatives have depleted. Suitable GMP rules must be defined. Because pathogenic and toxinogenic bacteria are apparently not a hazard for HMFP, especially due to the low pH as well as to the other hurdles hitherto applied,[7,66,70] the introduction of HACCP plans seems less appropriate than GMP rules for HMFP.

Guidelines are also useful for the design and the development of HMFP. For this purpose, Tapia de Daza et al. have recommended a 13-step procedure,[66,67] which resembles the 10-step guideline suggested for the design of hurdle technology foods by Leistner.[46] The user guide to design of high-moisture fruit products by hurdle technology as proposed by Tapia de Daza et al.[65,66,67] is outlined in Exhibit 14-3. Well-designed HMFP should lead to an autosterilization of the products during storage at ambient temperatures, by using mild but effective hurdles that secure microbial safety and stability as well as the sensory quality of HMFP.

Exhibit 14-3 User Guide to Design of High-Moisture Fruit Products (HMFP) by Combined Method

1. Proposal of the sensory properties, shelf life, packaging, and storage requirements of the desired product.
2. Suggestion of a tentative process technology for this HMFP.
3. Consideration of the properties inherent to the raw material:
   a. Microflora usually associated with this particular fruit
   b. Physical, biochemical, and chemical properties of this fruit
4. Outline of a preliminary process:
   a. Screening of the potential hurdles
   b. Performance of the potential process
   c. Predictive microbiology used in preliminary stability testing
5. Definition of prototype process based on results obtained in 4:
   a. Determination of process parameters
   b. Identification of hazards and weak process points
6. Manufacturing of the product according to process of 5:
   a. Microbial evaluation of the control points
   b. Evaluation of the final product properties
7. Storage studies (sensory, physical-chemical, microbial tests).
8. Isolation/identification of resistant microflora in HMFP.
9. Execution of challenge tests using relevant microorganisms.
10. If modifications of the hurdles are necessary start again with 6.
11. If modifications not necessary, final definition of the process.
12. Scaling-up of the applied process under industrial conditions.
13. Control of the industrial process according to GMP or HACCP.

Alzamora et al.[5] pointed out that the HMFP technology as developed in Latin America might give rise to an "explosion" of studies and applications of this innovative approach for fruit preservation in many developing countries. In this respect it is noteworthy that a preliminary study conducted in India already confirmed the results obtained in Latin America with HMFP. The Indian researchers concluded that "hurdle technology is seen as a promising technique for the preservation of fresh fruits and vegetables."[61]

Fish

The concept of hurdle technology is certainly also applicable for the preservation of fish; however, experimental work in this field is until now scanty. In several Latin American countries, fish is an important and often underutilized commodity as human food, and thus, interest in improved preservation methods is strong.

In Chile (Departamento de Ingeniería Química, Pontificia Universidad Católica de Chile, Santiago), the use of combined methods to extend the shelf life of sardines (*Sardinops sagax*) was studied by Aguilera et al.[2] Sardines and other pelagic fish from the western coast of South America are used mostly as raw material in fish meal production for animal feed. Their large-scale utilization as human food demands low-cost and simple processing and storage techniques. Therefore, the use of combined preservative factors was explored. The shelf life of minced sardines was extended from less than 3 days for the original unwashed mince to at least 15 days at 15°C by the following process: washing, addition of 6% sodium chloride (to obtain an a_w of 0.94) and 0.2% potassium sorbate, reduction of pH to 5.7 with acetic acid, packaging, and heat treatment of the product in a waterbath at 80°C for 2 minutes at the geometric center. The total count of the stabilized minced product remained very low during the whole storage period. Mincing of headed and gutted underutilized fish is considered to be an approriate process for their use as food. However, the mince of sardines, due to the light and dark tissues of this fish, is not attractive and therefore must be washed four times in order to remove dark pigments and the high fat content of sardines, and also to lower the microbial load by a factor of 100. The rather high salt content proved necessary for microbial stability, and the reduced pH contributed to inhibition of microbial growth primarily by increasing the effectiveness of sorbate. The mild heat treatment results in only minor changes in the textural and functional properties of the mince. The proposed hurdle technology food is considered to be an important alternative to traditional drying and/or salting, which stabilize the products but dramatically change the organoleptic properties of fish.[2]

In Argentina (Centro de Investigaciones de Tecnología Pesquera y Alimentos Regionales [CITEP], Mar del Plata), the application of hurdle technology for the preservation of fish was initiated at the beginning of the 1990s by Yeannes and coworkers, and several reports and papers on this subject have been published in Spanish or English since then.

Work was conducted with mackerel (*Scomber japonicus marplatensis*), anchovy (*Engraulis anchoita*), and salmon (*Pinguipes somnambulus*), in relation to the microbiology of the marination process, the microbiology and quality of intermediate- or high-moisture fish products, and the use of stabilized fish paste for making hamburgers, paté, etc. The results are applicable to fat and lean fish species, ie, mackerel and salmon, respectively. Some of these products are already on the market, for example, slices or chunks of salmon stabilized by salt, natural smoke, vinegar, potassium sorbate, and vacuum packaging, which are storable at least for 30 days at chill temperatures (Ing. Maria I. Yeannes, 1995; personal communication).

Two of the published research papers will be discussed. The microbiology of the marination process to be used for pelagic anchovy was studied by Fuselli et al.[21] The authors investigated different types of raw material (fresh, presalted, frozen), and each stage of an experimental marination process (sampling after washing the fillets, immersion into brine, immersion into a marinating bath, and packaging with acetic acid solution or oil), with the aim to extend the diversity of products made from anchovies. The results indicated that all types of raw material were suitable for marinating, and that the marination process (based on the combined preservative action of sodium chloride and acetic acid) was suitable to control the growth of pathogenic and spoilage bacteria, and thus might lead to a microbiologically stable product of good sensory quality. Because some bacteria survive the marination process, their behavior during the storage of the products was further investigated and will be reported later.[21]

Sanchez Pascua et al[63] studied the experimental development of an intermediate-moisture mackerel product with microbial stability based on the reduction of the water activity (caused by the addition of sodium chloride and glycerol), the addition of potassium sorbate, and a mild heat treatment. The fish was cooked for 20 minutes in the infusion solution (containing salt, glycerol, and sorbate) and afterwards was immersed in this solution for 20 hours at 2°C. The white muscle of the fish, with a_w of 0.89 and pH of 6.5, was packaged in glass jars with vegetable oil and pasteurized at 90°C for 40 minutes. The product obtained by this combined preservation process had a moderately sweet taste and a succulent texture; a bitter taste was not perceived. Therefore, such a product might be well accepted by the consumer. In future microbiological studies the shelf life of this product will be evaluated.[63]

Both of the quoted studies[21,63] from Argentina are of a preliminary nature. However, they indicate clearly that the application of combined factors might be useful for the preservation of fish in developing countries.

In Peru (Instituto Tecnologica Pesquero del Peru, Callao), a project on "Hurdle technology empirically applied in ancient and modern Peru" commenced (Dr. Guy Carvajal and Ing. Maria E. Ayala, 1996; personal communication). First, it was documented that in pre-Columbian times salting of fish was often used in combination with drying and smoking, as vestiges found at coastal Peruvian sites have attested. Still today, in the high plains of Peru, where the humidities are low, small whole fish are dried by traditional procedures. Another procedure used in ancient Peru for the preservation of food was the use of plants or essential oils from plants. During the time of the Incas, fish was covered with mint (*Mintostachys mollis*), a wild plant frequently encountered in the Peruvian Andean mountains, which has antibacterial and weak antioxidant properties. With this cover it was possible to transport fish without spoilage for two days at ambient temperatures. However, the mint extracts have been proven to be mutagenic.[13]

In recent decades other hurdles have been introduced, especially chilling (with ice) during transportation and storage, as well as heading and gutting of fish, which diminishes the bacterial load. In a novel process, the fish flesh (pulp) of sardines (*Sardinops sagax sagax*), horse-mackerel (*Trachurus symmetricus murphy*), or mackerel (*Scomber japonicus marplatensis*) is acidified with 0.5% to 2% citric acid and salted to contain 24.5% sodium chloride (a_w 0.75). After vacuum packaging, this product has a shelf life of at least three months at ambient temperatures. In order to delay rancidity of the lipids, the fish today is often dipped in antioxidants (BHA, tocopherol, etc) prior to salting or the antoxidants are added to the brine. Antioxidant-treated sardines may be stored with acceptable quality for one month at room temperature.

Another method used for preservation is fermentation. In Peru, silage for animal feed is obtained from cooked mince of waste fish, inoculated with yogurt bacteria and sugar cane is used as carbon source. A sugar concentration of 5% to 10% is enough to achieve a pH of 4.0 within two days at 40°C. Histamines slightly increased during incubation but decreased again during storage. The silage is stable and safe for at least 180 days at ambient temperatures, having an aromatic odor, which resembles fermented fruits. In Peru, work has been initiated to apply the hurdles mentioned as well as others systematically for the preservation of fish for human consumption (Dr. Guy Carvajal and Ing. Maria E. Ayala, 1996; personal communication).

Meat

In Latin America, a number of traditional intermediate-moisture meat products are common, eg, of the 260 foods studied in the course of the CYTED-D projects, 29 were meat products.[1] With the intention to improve the sensory quality of some of these meats, modifications based on combined preservative factors are at present under investigation.

In Brazil at the Universidade de Sao Paulo (USP) and the Universidade Estadual de Campinas (UNICAMP), experimental work is in progress to modify charqui, a typical Brazilian intermediate moisture meat product and an important source of animal protein, particularly for rural people in regions where refrigeration facilities are limited.[11,69] Charqui consists of large flat pieces of meat, mainly from the flank or forequarters of beef, preserved by salting and sun drying. The raw meat with a uniform thickness of 2–4 cm is submerged in a saturated salt solution for about one hour, and thereafter dry-salted in piles. To form a pile, marine salt is spread evenly on a concrete floor and then a layer of meat is put on the salt. The meat is covered with another (1 cm) layer of salt followed by another layer of meat, and so on until the alternate layers of salt and meat reach a height of about one meter. After eight hours, the pile is restacked so that the top meat goes to the bottom of the pile. The restacking process with fresh layers of salt is repeated every day for five days. Thereafter, the meat pieces are subjected to rapid washing to remove excess salt adhering to the surface. Now the meat is exposed to the sun on wooden rails for four to five days. At night, meat pieces are collected and stacked in piles on a concrete floor and covered with a tarpaulin.[40,57] Therefore, charqui is preserved by salting and drying, and it contains about 45% moisture and 15% sodium chloride, which results in an a_w of 0.70–0.75.[11,69] This traditional meat product is storable for several months without refrigeration. Charqui has a typical strong flavor and a slightly rancid taste. Fermentation during the drying phase, possibly caused by *Pediococcus halophilus*, might contribute to the typical flavor and as a hurdle to the preservation of charqui; however, this fermentation process is not well understood. On the other hand, it is known that halophilic bacteria might spoil (sour) the product.[40] If raw material of high quality is used, a gradual decrease of microbial counts during the processing and storage of charqui might occur. Thus, final products with low microbial levels are obtained if good raw materials and adequate handling conditions are used for charqui production and storage.[69] Charqui is always eaten in the cooked state. Full rehydration of the product before consumption is not possible even after prolonged soaking, but excess salt might be removed in this manner. The partially desalted charqui is often consumed as an ingredient for a typical Brazilian dish known as "feijoada," which contains black beans or rice and other desalted dried organs of beef or pork carcasses.[57,69]

The appearance, flavor, taste, and high salt content of traditional charqui today are not appealing to every consumer anymore, and therefore a derivative known as carne bovina salgada curada seca or jerked beef[11] was recently introduced to the market. As raw material for this product, meat from the forequarters of beef is stiched-pumped with a brine containing salt and nitrite, followed by dry curing and drying, and vacuum packaging of the finished product. Thus, the microbial stability and safety of jerked beef as well as traditional charqui is based on hurdle technology.[11] However, whereas in charqui, besides the a_w hurdle, a possible *Pediococcus* fermentation is only a minor hurdle; in jerked beef more hurdles have been introduced, resulting in sensory quality improvements. However, the hurdles necessary for the stability and quality of jerked beef are still regarded as too intense. Further investigations, also with similar products, are at the present time being conducted at the Universidad Estadual de Campinas (Prof. Bento da Costa Carvalho Júnior, 1996; personal communication).

14.3.2 China

China has a wealth of traditional foods, the recipes of many of those date back centuries. Moreover, China out of necessity and for culinary reasons makes use of a huge variety of raw materials as sources for delicious dishes and preserved food products. The microbial stability and safety of almost all of the latter are based on combined preservative factors empirically applied. However, because intentional hurdle technology (zang lan gi shu, in Chinese) was introduced by the author of this chapter, who is a permanent consultant to the Chinese Meat Research Center located in Beijing, interest in this innovative concept has grown. Some examples of recent applications of hurdle technology to meat products in China are subsequently discussed.

Meat

Work related to the application of hurdle technology on meat products is currently carried out in several Chinese research institutes (eg, Sichuan Provincial Research Institute of Animal and Veterinary Science, Chengdu; China Meat Research Center, Beijing; Hangzhou Institue of Commerce, Hangzhou; Heinaer Institute for Export Control, Inner Mongolia). Several recent publications in Chinese[51,73,74,75,82,83] have outlined the concept of hurdle technology, and thus made it popular in the People's Republic of China.

The per capita consumption of meat, compared to Western countries, is rather low in China. Nevertheless, because of the huge number of people living in China, this country has the highest meat consumption worldwide. Pork is the preferred meat in China; however, beef, water buffalo, sheep, duck, chicken, goose, rabbit, donkey, dog, and other species are used as raw materials.[40]

Only about 15% of the available meat of China is processed.[71] This is a large amount, and meat products are an important and precious part of the diet. There are two categories of meat products existing in China side by side: Chinese meats and Western meats. Western-type meat products were introduced to China during the last four decades. They are attractive because of their high yield, nice appearance, and pleasant taste. However, they still cause difficulties with respect to storage and microbial shelf life, because in China refrigeration is scarce and costly. Therefore, especially in the summer months, and if the microbial load of the raw material is too high or the hygienic conditions during meat processing are not adequate, spoilage and considerable economic losses frequently occur.[82] On the other hand, the traditional Chinese meat products are prevalent in China[71,72] because they are quite simple to prepare without expensive equipment, have a typical flavor, are ready-to-eat, and are storable without refrigeration. Some of the classical Chinese meat products, known for centuries, are listed in Table 14-4. The microbial stability and sensory quality of all of the products are based on combined preservative factors. Studies are in progress to identify the hurdles inherent to these traditional meats,[72] and thus an optimization of those products, if desirable, becomes feasible by the application of hurdle technology.[73]

The traditional Chinese meat products listed in Table 14-4 are all intermediate-moisture foods (a_w range 0.90–0.60). This implies that they might be too salty or too sweet, too tough and too dark due to the formation of Maillard reaction products. The water activity is the primary hurdle in these meats, but if additional hurdles are strengthened, then the a_w might be raised, which often improves the sensory

Table 14-4 Traditional Chinese Meat Products

Cured meats (Yan La)	Chinese bacon—La Rou Pressed duck—Ban Ya Silk rabbit—Cha Si Tu Cured chicken—Yuan Bao Ji
Dried meats (Rou Gan)	Dried meat—Rou Gan Sweet meat—Rou Pu Meat floss—Rou Song
Sausage (La Chang)	Guangdong La Chang, Sichuan La Chang, etc.
Raw ham (Ho Tui)	Yü Nam Ho Tui, Jin-Hua Ho Tui, etc.

Note: All of these meat products are intermediate-moisture foods and are storable without refrigeration.

quality of the products. However, the microbial stability and safety of the meats must not be jeopardized by an increased a_w. Therefore, intentional and intelligent hurdle technology is increasingly applied. Some examples of such endeavors are cited below.

Rou gan, a typical dried meat product of China, is prepared mainly from beef but also from mutton or pork, using a technology that has not been changed for hundreds of years, but improvements are possible and desirable. Consumers now prefer products with a softer texture, lighter color, and less sugar addition. Shafu is a modified dried meat that fulfills these expectations. The a_w of rou gan is in the range of 0.60–0.69, whereas shafu has an a_w of 0.74–0.76 because its moisture is higher and the sugar content lower. Additional hurdles in shafu are nitrite and ascorbic acid, which improve the color and delay rancidity, whereas rou gan is cured with nitrate only. Furthermore, the microbial stability of shafu is improved by the selection of raw material with low microbial load, low temperature during curing but relative high temperatures and shorter times during heating, and prevention of recontamination after the heat process as well as vacuum packaging of the final product in order to inhibit mold growth and to delay rancidity. Therefore, shafu is microbiological stable and safe for several months at ambient temperatures, and thus has the same shelf life as the traditional rou gan.[71]

A similar approach was chosen to improve the quality of Islamic dried beef in dices, which is also storable for several months without refrigeration. The traditional product is just salted and dried, and therefore is very salty and becomes easily rancid. The modified product contains less salt, is cured with nitrate to improve the color, and some ascorbic acid is added to delay rancidity. Furthermore, vacuum packaging is applied to reduce oxidation and to avoid mold growth.[78] These additional hurdles are very similar to those in modified charqui of Brazil, ie, jerked beef, discussed above.

Basic studies on the color,[79] flavor,[80] and taste,[81] using up-to-date methodology, have been conducted in China on the famous jin-hua ho tui. This is a traditional raw ham (Table 14-4) known for more than 800 years in China, and is much appreciated for its red muscle, white fat, characteristic flavor and taste, and the long shelf life.[79,80,81] Jin-hua ham resembles similar products of Europe (eg, prosciutto di parma of Italy, jamón serrano of Spain), and of the United States (eg, Virginia ham, country cured ham). All these bone-in hams are produced with a similar technology, cured with sodium chloride only and ripened under carefully controlled climatic conditions. They are characterized by a processing time of several months, which leads to the typical flavor (see Chapter 19). The microbial stability and safety as well as the quality of these raw hams are based on combined preservative factors, ie, a sequence of hurdles, which have been empirically applied to these products for centuries, but are today better understood.[37,38] Exhibit 14-4 presents guidelines for the production of traditional bone-in hams with a technology and preservative factors (hurdles) quite similar for products processed in Europe, the United States, or China.

Apparently the delicious flavor and the bright color of these hams are mainly caused by the activity of indigenous enzymes of the meat, without much participation of bacteria, yeasts, or molds. However, undesirable bacteria might lead to spoilage (which is most often caused by psychrotolerant Enterobacteriaceae) or even to food poisoning (caused by nonproteolytic *Clostridium botulinum* type B), if the green (fresh) hams harbor too many bacteria, have a pH >5.8, and are not kept <5°C until in all parts a NaCl content of >4.5% is achieved, which corresponds to a_w of 0.96. The finished products should contain not more than 5% to 7% NaCl.[37,38]

Presently, the NaCl content (8% to 15%) of jin-hua ham and similar products of other provinces of China is unnecessarily high with respect to safety and is detrimental to product quality.[72,73] Therefore, investigations are in progress to produce hams that contain less than 4% salt. However, with respect to the microbiological stability and safety, it is hazardous to lower the salt content of jin-hua ham below

Exhibit 14-4 Guidelines for the Processing of Traditional Bone-in Raw Hams of Europe, United States, and Asia

1. Careful transport and slaughtering of hogs (secures low initial counts of bacteria in the interior of the hams).
2. Chilling of hams in 24 hours to <4°C in the core (inhibits rapid growth of bacteria inside the hams).
3. Hams with pH >5.8 are excluded from raw ham production (thus meat with poor curing and high spoilage properties is eliminated).
4. Curing temperature in the first three months shall not exceed 5°C (inhibits bacteria inside hams during the curing process).
5. Hams are cured until in all parts a_w is <0.960; corresponds to >4.5% NaCl (inhibits bacterial growth in hams during ripening).
6. Ripening time is 7 to 20 months at 20°–25°C (30°C) (secures full flavor of finished products, which shall contain 5% to 7% NaCl).

Leistner, Shelf-Stable Products and Intermediate Moisture Foods Based on Meat, in *Water Activity: Theory and Applications to Food,* L.B. Rockland and L.R. Beuchat, eds., pp. 295–327, © 1987, Marcel Dekker, Inc.

5%, and to shorten the curing time at low temperature. Moreover, a shortcut of the subsequent ripening time at ambient temperatures might jeopardize the flavor of the products. Jin-hua ham, like other long ripened bone-in hams of Europe and America, is definitely a hurdle technology food product. The primary hurdle in these hams is the water activity. However, this hurdle becomes only slowly effective due to salt penetration and drying. Therefore, the initial bacterial counts in the hams must be low and growth of bacteria must be prevented by an initially low pH and strict refrigeration, until a critical a_w has been reached in all parts of the ham. Only then is it possible to raise the temperature, in order to speed up enzymatic ripening and flavor development of the product. The finished hams have an increased pH due to desired proteolysis, but the a_w is at this stage sufficiently low to secure a stable and safe product. Chinese researchers are now aware of the significant hurdles in jin-hua hams, and will take them into consideration in the course of their studies related to lowering the salt content and shortening the curing as well as the ripening time of jin-hua ho tui (Assoc. Prof. Shangwu Zhu, 1996, Hangzhou Institute of Commerce; personal communication).

A procedure that can be considered as an unusual variant of hurdle technology is now applied in the processing of frozen meat for export in such remote places as Mongolia.[51] This has improved the quality of expensive meat cuts from exotic wild animals (eg, Mongolian gazelles), by taking the following hurdles into account: initial microbial counts of the meat, water activity, redox potential, and temperature. Based on these hurdles an efficient process has been designed. The carcasses of shot animals arrive frozen at the meat plant, are cleaned, and the meat is frozen again. Freezing reduces the a_w and the microbial counts. For cutting, the meat is only partially defrosted; this avoids an increase of microbial counts as well as moist meat surfaces. This operation is carried out quickly under hygienic conditions. Then the meat with a temperature around 0°C is vacuum packaged, with careful exclusion of air in order to achieve a low Eh in the packages. Finally, the cuts are quick frozen at –25°C and shipped below –18°C without delay. The implementation of this process has much improved the microbial and sensory quality of such frozen cuts.[51] Therefore, this is a nice example of the practical and successful application of hurdle technology to frozen meat of China.

In Taiwan (Department of Food Science, Taichung University, Taichung), in cooperation with the German Meat Research Institute, hurdle technology was applied to stabilize la chang.[32] This Chinese sausage is highly esteemed by Oriental consumers, and differs from the fermented sausages common in Western countries because it is also processed raw, however, with only little fermentation. Several types of la chang (also called la zang or lup cheong) are known, eg, the Sichuan type is more spicy and the Cantonese type sweeter, whereas the Taiwanese la chang is softer. In mainland China, finished products of la chang have the following properties: a_w 0.85–0.70, pH 5.9–5.7, salt 3% to 5%, sugar 4% to 20%, total count $<10^6$ g^{-1}, and shelf life two to three months without refrigeration and, if vacuum packaged, even four to five months. To the coarsely ground meat and fat from pork, sugar, salt, soya sauce, liquor, spices, nitrate (or nitrite), and sometimes sodium ascorbate are added. The mix is stuffed into casings with small diameter, and the sausages are dried fast over charcoal at 45°–60°C to a_w of 0.92. They are then further dried at ambient temperature to a_w <0.80 in order to avoid an increase of the lactic acid bacteria counts because generally the Chinese dislike sour meats. Thus, la chang is a typical meat product preserved by combined factors. In general, before consumption la chang is sliced and heated in rice or vegetable dishes.[32,38,72,73] Angkak is often added to Chinese sausage. This is rice fermented with *Monascus* spp., which contains red pigments as well as flavoring and antimicrobial metabolites. The pigments are heat, light, and pH stable, whereas the antimicrobial substances inhibit definitely Gram-positive and moderately also Gram-negative bacteria,[41,43] and thus angkak could be considered to be an additional hurdle applied in la chang.

The Taiwanese variety of Chinese sausage contains more moisture, and therefore can have an a_w as high as 0.94. This improves the sensory properties because the products are softer. However, it decreases their microbial stability and safety because in such products lactic acid bacteria still grow and lead to a sour taste, and *Staphylococcus aureus* might cause food poisoning. After addition of 3.5% sodium lactate and 0.1% sodium acetate, the Taiwanese sausage remains tasty but is rendered microbiologically stable and safe, even if stored for several weeks without refrigeration. These additives reduce the a_w of the products but also have some antimicrobial effects.[32] Challenge tests using inocula of *Staphylococcus aureus*, *Listeria monocytogenes*, or *Salmonella* spp. confirmed these effects, and demonstrated that during storage at 25°C, the number of pathogens decreased faster than at 10°C.[32] The latter was probably due to a faster metabolic exhaustion of the pathogens at the higher storage temperature.[47]

Chinese meat technologies are also employed in other Asian countries, such as Singapore, Malaysia, and the Philippines, but with local variations. Also, in Western countries with Asian minorities, Chinese meat products are increasingly on the market. In general, for developing countries the traditional Chinese meats as well as Chinese meat products optimized by intelligent hurdle technology should be of interest, especially if meat products must be stored without refrigeration. Because Chinese meat technology is based on different principles, but also results in safe, stable, and high quality products, it might be a source of innovation for Western countries. On the other hand, novel hurdle technology meats developed in Western countries have been already implemented in China. For example, shelf-stable heated meat products of the F-SSP type[36,44] are now produced in large quantities in the Luoyang city and other regions of China.

14.3.3 India

Lectures in India by the author of this chapter on food preservation using combined preservative factors, as well as reports on this subject published by Indian scientists[8,29,60,61] have stimulated research about the application of hurdle technology to traditional and modified Indian food products. Work related to food preservation using hurdle technology is at present carried out at several research institutes of India (eg, Central Food Technological Research Institute (CFTRI), Mysore; BHABHA Atomic Research Centre, Food Technology Division, Trombay (Bombay); Indian Institute of Technology, Bombay; University of North Bengal, Siliguri; National Dairy Research Institute (NDRI), Karnal).

Dairy Products

In India, vegetarian food is common, but dairy products are also much appreciated. Some recent examples of the application of hurdle technology to Indian dairy products are discussed.

Paneer is a traditional, cottage cheese–type product fried in cubes with oil and onions, to which a sauce containing salt, spices, and often tomatoes is added. This food is frequently consumed and much liked in the Northern provinces of India because of its nutritive value and characteristic taste. However, paneer spoils bacteriologically within one to two days at room temperature (which in India can reach 40°C), which is a strong drawback for its industrial production. Sterilized paneer in cans has severe sensory limitations with regard to flavor, texture, and color. Therefore, together with a visiting scientist from India, Dr. K. Jayaraj Rao, in the German Meat Research Institute, Kulmbach, a mildly heated paneer in hermetically sealed containers, with the desired flavor (like prepared fresh), color (little browning), and texture (not too hard) was developed.[59] This product was stabilized by hurdle technology, and thus is stable and safe for several weeks without refrigeration. The following combinations of hurdles proved effective with this product: a_w = 0.97, heating to F_0 value of 0.8, pH = 5.0 or alternatively a_w = 0.96, F_0 = 0.4, pH = 5.0.[59] After his return to India, Rao conducted a thorough study on the application of hurdle technology to fried paneer in cubes made of buffalo milk. The product with gravy was packed either in tins or flexible retort pouches, and a set of hurdles, ie, a_w = 0.95, F_0 = 0.8, pH = 5.0, and 0.1% potassium sorbate, was chosen, which had maximum lethal and inhibitory effects on microorganisms and minimum effects on textural and chemical characteristics.[60] The water activity of paneer and gravy was lowered by using humectants, such as *dahi*, skim milk powder, salt, and glycerol. The pH was adjusted by changing the *dahi*/skim milk powder ratio. The resulting product had a keeping quality of two weeks at 45°C, one month at 30°C, or over three months at 15°C, which was limited by textural changes (hardness, cohesiveness, gumminess, springiness, and chewiness) as well as by chemical changes (browning, oxidation, lipolysis, and loss of available lysine), but not by microbiological spoilage. A mathematical shelf life prediction model based on sensory scores and quality parameters was developed. The stabilized product was compared with fresh samples from restaurants and was found to be equally acceptable. In the opinion of Rao,[60] this method of paneer preservation has a large scope for alterations in product formulations depending on regional taste preferences, without affecting the keeping quality of the product. Via paneer, the hurdle technology was introduced into food science of India, and its application to other indigenous foods is now anticipated.

A recent example is dudh churpi, a popular dairy product of the Himalaya region of India (ie, Bhutan, Sikkim, Darjeeling), made of milk from yaks or cows. This product is stable for several months without refrigeration. Most important for dudh churpi is the texture (elasticity), because people living in high altitudes chew it as an *energy tablet*. The sensory quality and microbial stability of dudh churpi was optimized by Hossain[29] using combined methods (hurdle technology) of heating, acid coagulation, addition of sugar and sorbate, smoking, drying, and packaging in closed containers. In this detailed and diligent study, dudh churpi was scientifically explored and a feasible optimization of the product was suggested. Thus, hurdle technology was applied to improve a traditional food of the remote Himalayan region. At the same time, the scientific basis of this study opened new avenues for food science and industrial food production in India. Hurdle technology is perceived now by some Indian scientists as the most appropriate technology for preserving foods in developing countries (G.R. Patil, 1992; personal communication).

14.3.4 Africa

The author of this chapter introduced the application of hurdle technology for the preservation of shelf-stable foods during an invited lecture presented in 1988 at a meeting of the South African Association for Food Science and Technology.[39] Since that time this concept was successfully applied to various food products, especially by Dr. Alexander von Holy and his group (Department of Microbiology, University of Witwatersrand, Johannesburg). A recent example is the prevention of spoilage (ropiness) of bread that results from the growth of amylolytic *Bacillus* species, which causes significant losses to the baking industry in South African conditions. By the addition of calcium propionate in combination with vinegar to the dough, reducing the spore counts in the raw materials and on the equipment, and temperature control during and after baking, it was possible to avoid the ropiness of bread. This is considered to be a practical application of food preservation using combined methods.[28] In another recent study on the spoilage of vacuum packaged Vienna sausages resulting from the growth of lactic acid bacteria during storage, it was investigated whether an in-package pasteurization of the products at about 60°C could delay spoilage. This was indeed possible if the products were stored at 8°C. However, the pasteurization processes studied decreased the occurrence of leuconostocs and homofermentative lactobacilli more than pediococci, and increased the incidence of bacilli and clostridia. The presence of *Clostridium perfringens* in pasteurized samples indicated that in-package pasteurization of Vienna sausages could compromise product safety if the temperature was allowed to rise.[20] Since the political situation in South Africa has changed, it is anticipated that food science and technology of neighboring African states will be fostered by cooperation with South Africa. Thus, the application of combined methods (hurdle technology) for food preservation will probably now spread.

However, in some African countries researchers are already aware and interested in the application of hurdle technology for the preservation of foods. For instance, Dr. Bernard O. Ejechi and his group (Department of Microbiology, Delta State University, Abraka, Nigeria) are working on the preservation of various food items by means of combined methods.

Tomatoes, which are abundant in Nigeria only at certain times of the year, are often minced with salt in the home, boiled, covered with a thin layer of groundnut or palm oil, and then stored for several weeks at ambient temperatures because refrigeration is too expensive. This traditional hurdle technology food has the drawback that the supply of oil is scarce because it is needed for cooking. Therefore, oil should be replaced by preservatives that the average consumer can afford. Because nutmeg, vanilla, and pepperfruit seeds are readily available in Nigeria, the preservative effects of their aqueous extracts were investigated. In addition, the sodium chloride addition and the heat treatment of the tomato blend, in relation to the sensory quality of the product, were standardized. By using tomato-rot fungi (*Candida* species, *Saccharomyces* spp., *Geotrichum* spp., and *Rhizopus* spp.) for challenge tests, it was established that by the following hurdle combination a shelf life of three months at room temperature of the tomato blend and a good sensory quality of the product were achieved: addition of 2% sodium chloride and 1% aqueous extract of pepperfruit (*Dennetia tripetala*) seeds, and a heat treatment at 60°C for 30 minutes.[18]

Furthermore, the Nigerian researchers accomplished a shelf life of three months of orange and pineapple juice with the following hurdle combination: addition of spice extracts from nutmeg, vanilla, or ginger and heat treatment at 70°C for 5 minutes. However, color changes of the juices caused by the spices are undesirable; therefore, sodium metabisulfite was added in small amounts, which allows for reducing the level of added spice extracts. With mango juice, a shelf life of three months was achieved, after addition of aqueous extracts (4%) of spices (ginger, nutmeg) combined with a mild heat treatment (50°C for 15 minutes), and in this case the sensory quality of the juice with the added spice extracts was acceptable (Dr. B.O. Ejechi, 1996; personal communication).

In Nigeria soya bean milk is increasingly used as baby food, especially among the low-income groups because conventional baby food is expensive. Therefore, the microbial stabilization of this easily perishable food is also an issue. The hurdles considered for preservation of soya bean milk are the addition of lemon juice (5%) and sodium chloride (1%) combined with a mild heat treatment (50°C for 5 minutes), or the addition of aqueous ginger extract to improve the flavor and possibly the shelf life of this food (Dr. B.O. Ejechi, 1996; personal communication).

Thus, combined methods were explored recently for the preservation of various foods in Nigeria, and it is noteworthy that "natural" preservatives, like spice extracts, are preferred to chemical preservatives because they are readily available and less expensive.

14.4 CONCLUDING REMARKS

The microbial stability and safety as well as the quality of almost all foods in developing countries is based on a combination of preservative factors (hurdles). Such preservation processes have been applied empirically since time immemorial to traditional foods, which are often intermediate-moisture foods (a_w range 0.90–0.60), and storable without refrigeration. Of course, refrigeration is known in developing countries; however, energy is very expensive and not continuously available and, therefore, foods microbiologically stable and safe without refrigeration are much preferred.

In developing countries the hurdles are chosen intentionally because of better understanding of the hurdle effect, and thus, the preservation of foods is optimized by the application of hurdle technology. Such foods are often in the high-moisture range (a_w above 0.90) and have an improved sensory quality, but are storable without refrigeration. It is a general trend in developing countries to move gradually away from intermediate-moisture foods because they are often too salty or too sweet, and have a less appealing texture and appearance than high-moisture foods. Thus, it is expected that fresh-like, high-moisture foods, which are nevertheless storable without refrigeration, will be on the increase in developing countries as soon as the application of hurdle technology has been mastered. In the opinion of an Indian food scientist, the most appropriate technology for preserving foods in developing countries is the application of hurdle technology.

However, use of hurdle technology should not lead to the addition of high levels of additives, but actually should reduce the amounts of additives used even if their number might increase. It is important that additional hurdles be introduced into a food product only after careful consideration of the necessity and in essential amounts, otherwise an undesirable chemical overloading of the food could result. Under artisan conditions especially, there is sometimes an indiscriminate use of chemical food additives, eg, sulfite to fruits or nitrate to meats, and such shortcomings must be prevented in modified hurdle technology foods. If possible, "natural" additives such as spices or herbs and their extracts should be employed because they are more consumer friendly, easily available, and less expensive in developing countries than chemical preservatives.

Hurdle technology foods are in general less robust than traditional food products, which are often overprocessed and thus provide for a large margin of safety. Therefore, if modified hurdle technology foods are produced, the applied processes must be exactly defined and controlled. It is essential that soundly based challenge tests be applied before new hurdle technology foods are exploited in developing countries. Furthermore, strict guidelines must be employed in the processing of hurdle technology foods. The application of the Hazard Analysis Criti-

Next Page

cal Control Point (HACCP) concept still faces practical difficulties in developing countries, where many small producers prevail. However, guidelines based on Good Manufacturing Practice (GMP) are essential and often will be sufficient. The definition and control of such guidelines must be backed up by objective monitoring of the governing preservative factors, and even in small enterprises in developing countries, the most important of the preservative parameters such as time, temperature, pH, and a_w must be defined and should be quantitatively measured.

In recent years, impressive results have been achieved because of the introduction of hurdle technology for the microbial stabilization and sensory improvement of high-moisture foods in several countries of Latin America, especially fruits. But similar developments have started recently related to meat products of China and Argentina, as well as dairy products of India and miscellaneous foods of Africa. However, most of these developments are still in the pilot plant stage, but the industrial production of these modified or novel foods should be accomplished. If hurdle technology was employed on an industrial scale, seasonal surpluses of certain food commodities, such as fruits, could be accommodated, and therefore, post-harvest spoilage and waste of precious foods could be avoided, and fresh-like products would be available for consumption or further processing during the entire year.

Latin American researchers believe the application of intentional hurdle technology for food preservation might lead to an "explosion" of research and development of novel, minimally processed foods. On the other hand, if the time-honored preservation principles of traditional foods of developing countries become better understood, then food science in general would benefit, and traditional foods of developing countries might become a source of innovation for novel foods of industrialized countries.

Intentional hurdle technology might open up a new dimension of food preservation for both developing and industrialized countries. However, to achieve this goal more basic research is needed, which should focus on a better understanding of the homeostasis, stress reactions, and metabolic exhaustion of microorganisms, and especially on multitarget preservation of foods. The latter probably is the key for a breakthrough in the use of a truly intelligent application of hurdle technology. Analogous to the *combination therapy* in the medical field, which produced hopeful results in the use of chemotherapeutic drugs against tuberculosis, cancer, and recently HIV infections too, the *multitarget preservation* of foods[47] could be the most promising strategy for future food preservation in both industrialized and developing countries.

15.1 INTRODUCTION

The various methods used to preserve food are designed either to inactivate microbes of concern or to inhibit or prevent their growth. Organisms that survive such treatments may be injured so that they become more exacting in their growth requirements and fail to grow on the selective media normally used in their isolation. Under suitable conditions, injured cells can repair cellular damage and recover all their normal properties including virulence. An appreciation of the nature of sublethal injury and its repair is therefore important in detecting and enumerating foodborne microbes and in devising food preservation strategies.

Another class of microorganisms that have given rise to concern are those that enter the so-called viable but nonculturable (VBNC) state in response to starvation or other stresses. Such organisms lose their ability to grow on nutrient nonselective media that normally support their growth, but are believed to be viable because the cells remain physically intact and exhibit metabolic activity of various sorts. The suggestion that such organisms are capable of causing disease has serious implications in epidemiology and monitoring for food safety, but the physiological basis of the VBNC condition and its relationship to injured or dormant states is presently unclear.

15.2 DEFINITIONS OF VIABILITY, DEATH, AND SUBLETHAL INJURY

In microbiology, definitions of viability are usually based on the ability of organisms to multiply. Alternative definitions, based for example on the maintenance of homeostasis in single cells, are possible in principle but at present pose insuperable problems of measurement. Because viability is defined by the method of measurement, recovery conditions and the method for assessing cell multiplication must be specified. Colony formation or production of turbidity in broth are the usual criteria but there are numerous examples where cells may undergo limited multiplication to produce microcolonies on agar or final cell densities in liquid media that do not cause visible turbidity. The limitation of all definitions based on growth on or in laboratory media is that they exclude all those organisms that have not yet been cultured, estimated to comprise 90% or more of all microbes that inhabit the earth.[131] (Species that have been identified by gene probes but not yet cultured are often referred to as *hidden communities.*) Death of microbes may be defined as an irreversible loss of the ability to generate progeny. Sublethal injury can be reversed or circumvented whereas lethal injury cannot.

15.3 THE NATURE OF SUBLETHAL INJURY

15.3.1 Characteristics of Injured Bacteria

Many early workers described changes in the growth properties of bacteria following exposure to inimical conditions. An extended lag phase was observed in cells surviving heat or cold treatment[39,48,71] and more fastidious nutritional requirements for recovery were seen in heat-damaged or freeze-injured vegetative cells or spores.[40,70,124,167,175] The widespread use of selective enrichment media began in about 1920 but the limitations of these media in recovering stressed cells were not fully appreciated until quantitative studies revealed poor recovery of cells following freezing,[66] heating,[95] or drying.[127] Sublethal injury and its repair have been reviewed in numerous articles and book volumes.[5,16,30,75,77,120,168] Table 15-1 summarizes the characteristic features of injured vegetative cells and attempts to explain their altered growth properties in terms of damage to specific cell structures or functions.

15.3.2 Damage to the Gram-negative Outer Membrane

The outer membrane of Gram-negative bacteria protects the cell against lytic enzymes, bile salts, and certain antibiotics, but allows low molecular weight nutrients to diffuse into the periplasmic space where they may be taken up by transport systems present in the cytoplasmic membrane (Figure 15-1). If the outer membrane is damaged, cells become sensitized and unable to grow on selective media containing bile salts or triphenylmethane dyes (eg, MacConkey or Brilliant Green agars). Injury of this sort is typical of cells exposed to heat, cold shock, freezing, drying, aerosolization, and high pressure.

The phenotype of such injured cells resembles that of enteric organisms that have defects in the lipopolysaccharide (LPS) component of the outer membrane, arising from mutation or treatment with EDTA. Increased sensitivity to hydrophobic antibiotics in these cells is attributed to a conformational change resulting in exposure of hydrophobic regions on the outer membrane surface.[125] The corresponding structural basis of damage caused by physical treatments is not yet known. Loss of LPS has been seen in heat- or freeze-injured *Escherichia coli* and *Pseudomonas* cells,[72,158] and a conformational change in the outer membrane of freeze-injured *E. coli* was indicated by an altered pattern of adsorption of LPS-specific bacteriophages.[89,148] Increases in cell surface hydrophobicity and sensitivity to hydrophobic antibiotics were demonstrated in *E. coli* cells injured by heating, freezing, drying, or gamma-radiation.[103] However, changes in surface hydrophobicity alone would not be sufficient to account for the increase in sensitivity to vancomycin and lysozyme (which are large hydrophilic molecules), the leakage of periplasmic enzymes, or the increased permeability to dextrans of molecular mass 60,000–90,000.[32] Such gross changes in permeability suggest the creation, at least temporarily, of small holes or pores in the outer membrane.

15.3.3 Damage to the Gram-positive Cell Wall

Gram-positive organisms do not possess an outer membrane but some species have a surface protein layer that appears to have an analogous protective function. For example, in Gram-positive organisms that inhabit the gut, possession of a surface layer provides protection against bile salts and lytic enzymes. Freeze injury to *Lactobacillus bulgaricus* re-

Table 15-1 Sublethal Injury in Vegetative Cells

Symptom of Injury	*Suggested Cause of Injury*
Sensitivity to acid, alkali, osmotic stress; and some inorganic ions (eg, selenite, copper) Leakage of UV-absorbing material	Cytoplasmic membrane damage
Sensitivity to bile salts, triphenyl methane dyes, hydrophobic antibiotics, lytic enzymes Leakage of periplasmic enzymes	Damage to Gram-negative outer membrane or Gram-positive surface protein layer
Sensitivity to oxidative stress	Inactivation of catalase, superoxide dismutase Increased metabolic production of H_2O_2 or O_2^- Loss of cofactors for DNA repair enzymes Loss of intracellular reductants
Altered nutritional requirements for growth (real or apparent)	Enzyme inactivation (eg, peptidases) Membrane damage leading to sensitivity to Cu^{++} or growth stimulation or inhibition by amino acids Sensitivity to peroxide in rich media Metabolic imbalance on nutritional upshift
Altered metabolism	Enzyme inactivation Membrane damage leading to changes in enzyme/substrate accessibility
Increased frequency of mutation	Damage to DNA
Restricted temperature range for growth Increased sensitivity to secondary stress	Imbalance between repair and degradative processes (?)
Loss of virulence	(?)
Extended lag	Need to resynthesize damaged membranes, nucleic acids, ribosomes, etc

sulted in loss of surface protein and increased sensitivity to Tween 80.[197]

The cell wall of *Staphylococcus aureus* contains negatively charged teichoic acid polymers that bind magnesium. When heated in phosphate buffer, cells lost magnesium and D-alanine from wall teichoic acid.[74] In the absence of alanine, teichoic acid binds magnesium so strongly that it becomes unavailable for metabolic processes required for growth. If alanine is withheld from heat-injured cells, subsequent growth is very slow and occurs only after a long lag.

15.3.4 Damage to the Cytoplasmic Membrane

An intact cytoplasmic membrane is essential for the maintenance of homeostasis under fluctuating external conditions. Cells with damaged cytoplasmic membranes are inhibited by pH values or salt concentrations that would normally permit growth, and are hypersensitive to traces of copper in diluents or media. These symptoms of injury are associated with almost all forms of physical stress and could, in principle, be due to (1) gross loss of structural integrity or (2) loss of specific permease functions.

Gross damage is indicated by leakage of UV-absorbing material from the cell or increased access of molecules to the cytoplasmic compartment. Leaked material includes K^+, inorganic phosphate, phosphorylated sugars, sugars, fatty acids, esters, and amino compounds. An impression of the extent of injury is obtained from the size of molecule able to pass across the membrane. The cytoplasmic enzyme glucose-6-phosphate dehydrogenase was unable to escape from freeze-injured *E. coli*, whereas molecules of molecular mass 12 kD (ribonuclease) but not 16 kD (dextrans) were able to enter the cell from out-

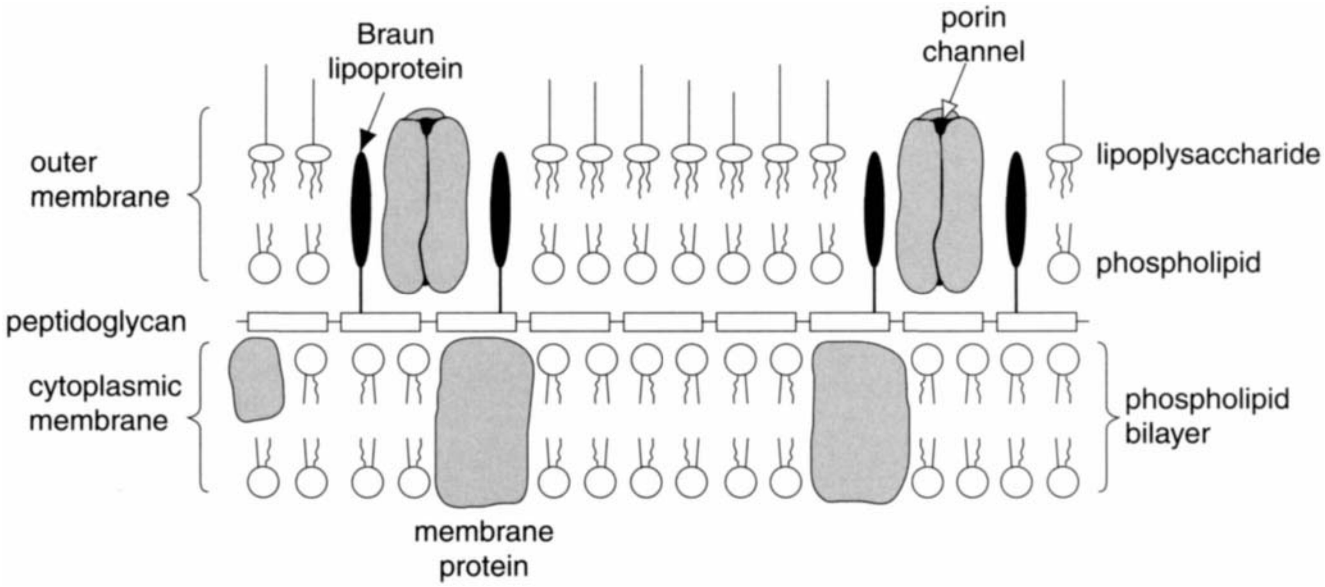

Figure 15-1 Schematic Representation of the Cell Envelope of an Enteric Gram-negative Bacterium.

side.[112,176] The amount and nature of material that leaks from damaged cells depends on the stress conditions. For example, cells of *Escherichia coli* frozen in water at freezing rates below 6°C/min lost no UV-absorbing material whereas above this rate, the release of UV-absorbing material was inversely related to survival. Leakage was not observed in acid-injured cells of *Salmonella bareilly* or *E. coli*.[22,143]

Gross structural damage in the form of loss of lipid and other membrane components during heating or freezing has been demonstrated in *E. coli* and *Staphylococcus aureus*.[78,170] By contrast, no lipid loss was detected in *Salmonella typhimurium* heated at 48°C, although cells became sensitive to eosin-methylene blue medium containing 2% NaCl.[180] During repair of heat injury, *de novo* synthesis of membrane lipid has been shown in *Salmonella typhimurium* and *Staphylococcus aureus*, and in both there was an increase in the proportion of unsaturated fatty acids in phospholipid synthesized during repair.[181]

Visual evidence for membrane damage in *E. coli* has been obtained by using light or electron microscopy. Cells exposed to mild heat released membrane vesicles into the medium, whereas cells exposed to hypotonic stress shed small membrane vesicles *into* the cytoplasm.[163,183] In pressure-treated *Listeria monocytogenes*, visible evidence of membrane perturbations took the form of large clear areas in the cytoplasm adjacent to membranes, suggesting that membrane invaginations had occurred under pressure.[109] In both bacteria and yeasts, rapid water movements in response to sudden changes in water potential cause loss of viability attributed to damage to the cytoplasmic membrane.[113,138]

Loss of homeostasis could also result from loss of specific membrane functions in an otherwise intact membrane. Alterations in the uptake or efflux of sugars and amino acids have been reported in several bacterial species and, in yeast, sublethal injury causes a lowering of the intracellular pH.[38,63,78,136] Partial inactivation of membrane-bound ATPases occurred during pressure treatment of *Lactobacillus plantarum*,[169] and a key role for this enzyme in thermotolerance of the yeast *Saccharomyces cerevisiae* has been postulated.[38]

The cytoplasmic membrane is clearly an important target for damage by inimical treatments but it is not yet clear what distinguishes lethal from sublethal damage. Temporary loss of permeability control is not necessarily fatal, as seen in electroporated cells that are permeable to large DNA molecules but can recover full viability if incubated in a favorable medium, as can those damaged by bacteriocins.[188] Membrane damage presumably becomes lethal if (1) the damage is of a nature that precludes resealing, or (2) irreversible effects occur as a secondary consequence of loss of permeability control, energy conservation, or other membrane functions. Loss of magnesium can lead to the destabilization of ribosomes and failure of DNA repair processes, while loss of other cofactors will disrupt normal metabolic control processes. If this perturbed condition persists for long enough and the supply of energy is curtailed, the degenerative changes become impossible to reverse and cell death ensues. Irreversible effects are especially likely when the external environment differs markedly from that of the cell or when inhibitors or other deleterious agents are present in the medium. In any population of injured cells, there is a spectrum of sensitivity to salt, pH, or other agents, implying varying degrees of membrane injury, but the physical basis of this is completely unknown.

15.3.5 Damage to DNA

Damage to DNA is the primary cause of cell death in microbes exposed to ultraviolet or ionizing radiation. Ultraviolet light, particularly at 250 to 260 nm, is absorbed by nucleic acids, giving rise to cyclobutane pyrimidine dimers that distort the DNA helix. Ionizing radiation causes a wide range of damage products in DNA, but the most important biologically are single- or double-strand breaks. *Escherichia coli* can remove up to 850 pyrimidine dimers and can repair up to 30 single-strand breaks per genome in the exponential phase.[119] *Deinococcus radiodurans* is exceptionally resistant to UV and ionizing radiation and can deal with around 12,000 pyrimidine dimers and up to 3,000 single-strand or 240 double-strand breaks. DNA damage is therefore sublethal up to the point where the repair systems become saturated. The ability of repair systems to cope with the damage is influenced by post-injury holding conditions. Survival is enhanced if irradiated cells are incubated in buffer before plating out because this allows more time for repair before chromosome replication is attempted. As a general rule, plating media that support rapid growth result in the lowest recoveries of irradiated cells. The optimum temperature for recovery of irradiated bacteria is strain dependent but is often lower than the optimum for growth. Survival of gamma-irradiated cells of *Escherichia coli* B/r was thus maximal around 18°C, compared with a growth optimum of 37°C.[88]

DNA damage has also been reported in heated, freeze-thawed, dried, and acid-treated cells, measured directly as single- or double-strand breaks, or inferred from an increase in the mutation frequency, or greater sensitivity to stress of mutant strains defective in DNA repair processes.[8,28,106,135] DNA damage can occur directly as a result of acid-catalyzed deamination or depurination,[99] or indirectly, caused by nuclease action. Mutants of *E. coli* lacking the *xthA* encoded apurinic endonuclease were more resistant to heat and sustained fewer strand breaks in their DNA than the parental strain.[64]

The significance of DNA damage in death caused by heating, freezing, drying, or acid is not clear. The number of strand breaks reported in freeze-injured *E. coli* at 50% survival was only about three,[3] a number easily repaired in irradiated cells. If repair systems were also inactivated by the stress treatment, a low number of lesions normally regarded as sublethal might become lethal. In cold-shocked cells, death was attributed to loss of magnesium that is required for the action of DNA-ligase, an enzyme involved in DNA synthesis and repair.[160]

With ionizing radiation damage it has been possible to relate recovery of viability to repair of DNA by performing fractionated dose experiments in which recovery after a set dose of radiation is increased if an interval for DNA repair is allowed during the administration of the dose.[54] There are no corresponding data relating DNA repair to recovery of cells damaged by other agents, but the release of heat-shock proteins from the nucleoid of heat-injured *E. coli* during incubation in broth at 37°C was correlated with recovery of ability to grow on agar plates.[135]

15.3.6 Damage to Ribosomes and RNA

Loss of ribosomes occurs in heat-injured and starved cells especially under conditions that lead to depletion of intracellular magnesium. When cells of *Salmonella typhimurium, Staphylococcus aureus, Pseudomonas fluorescens,* or *Agrobacterium tumefaciens* are heated in phosphate buffer at relatively mild temperatures (48°–50°C) selective destruction of the 30S ribosomal subunit and 16S RNA is observed.[76,181] This effect is attributed to destabilization of ribosome structure by loss of magnesium followed by nuclease attack. Destruction of the 30S subunit is prevented when magnesium is added to the buffer in which cells are heated. Loss of the 30S subunit is not necessarily lethal under these mild heating conditions and resynthesis of 16S RNA and ribosomal proteins can occur when cells are incubated in growth medium at 37°C. Death of exponential phase cells of *Salmonella typhimurium* at 52°C was accompanied by extensive degradation of 16S RNA. Starved cells or those grown in the presence of 100 mM $MgCl_2$ were not killed under the same heating conditions and retained 16S RNA, hence it was concluded that degradation of ribosomal RNA is a direct cause of cell death. Studies of cells heated at rising temperatures in the differential scanning calorimeter showed that loss of viability in *E. coli* and *Listeria monocytogenes* was associated with irreversible destruction of the 30S subunit at higher temperatures.[4,110] Loss of the 30S ribosomal subunit can thus be lethal or sublethal depending on heating and recovery conditions. This form of injury is associated with an extended lag time during which RNA and protein are resynthesized.

15.3.7 Altered Nutritional Requirements for Growth

Injured cells usually recover better on rich than minimal media. The added nutrients may aid recovery simply by removing some of the metabolic burden from injured cells, but in freeze-injured *Escherichia coli* and *Streptococcus lactis*, specific requirements for amino acids or peptides were identified.[106,133] In some strains of *E. coli*, failure to grow on minimal medium was not a nutritional effect. Cells with damaged membranes were sensitive to traces of copper ions present in water used to make the media, and in rich media, copper ions were chelated by amino acids and hence detoxified. A quite different example of an apparently altered nutritional requirement after exposure to stress was seen in *E. coli* cells treated with N-ethylmaleimide.[182] Following exposure to this compound, cells lost the ability to grow on minimal agar but could do so after supplementation with peptone. This was not a nutritional effect because different peptones, each of which was sufficient to support good growth, differed in their ability to prevent loss of colony-forming ability on plates. It was suggested that depletion of intracellular glutathione caused cells to be sensitive to reactive oxygen intermediates, and peptides served a protective function in place of glutathione.

Most bacteria in marine samples are unable to grow on rich nutrient media, but may develop the ability to do so after prolonged storage in the stationary phase or on subculture to progressively higher nutrient concentrations.[53,162] The oligotrophic phenotype appears to be associated with adaptation to low nutrient conditions and possession of very high affinity uptake systems, but the physiology is poorly understood. The phenomenon of substrate-accelerated death in starved copiotrophic bacteria is well documented[43,142] but the significance of *metabolic imbalance* in recovery of stressed cells generally, requires clarification.

15.3.8 Sensitivity to Oxidative Stress

The sensitivity of injured cells to oxidative stress is of major importance in their detection and survival but is often little appreciated. Exposing complex growth media to light in the presence of air results in the photochemical production of peroxide and superoxide whose presence is lethal to injured cells. The addition of catalase or pyruvate removes peroxide and improves recovery of injured Gram-positive and Gram-negative bacteria.[115] Incubation of heat-injured cells under strictly anaerobic conditions also dramatically improved recoveries of *L. monocytogenes, E. coli* O157, *Staphylococcus aureus*, and *Salmonella enteritidis*.[55,92]

The phenomenon of *minimal medium recovery* may also be interpreted as an effect of oxidative stress. Under some conditions injured cells recover better on minimal salts media than on a rich media such as tryptone soya agar. This occurs in cold-shocked or heat-injured Gram-negative bacteria, but is usually seen only when cells are (1) grown in a minimal medium and (2) stressed during the exponential phase of growth. Cells exposed to the rich medium apparently die as result of oxidative damage to DNA caused by traces of peroxide present in the medium.[57,107]

The increased sensitivity to oxidative stress from exogenous sources could be caused by increased susceptibility of target sites to oxidative attack or decreased efficiency of protective mechanisms. Inactivation of catalase and superoxide dismutase has been recorded in heated cells of *Staphylococcus aureus* and *E. coli*, but the relationship between loss of enzyme activity and sensitivity to oxidative stress and/or sensitivity to heat is not simple. Heating *S. aureus* at 52°C for 45 minutes reduced viable counts by 90% but reduced superoxide dismutase activity by only 10%.[29] Catalase activity decreased only slightly during heating at 52°C, but a much greater decrease occurred during the first two to four hours of repair in tryptone soya broth.[6] In *E. coli*, increased sensitivity to micromolar concentrations of peroxide in heat-injured cells was not correlated with loss of total catalase activity but matched the decline in activity of the inducible hydroperoxidase I.[108] Relatively mild dilution shock may also render cells susceptible to oxidative stress,[107] suggesting that other factors may also be involved, eg, loss of cofactors needed for DNA repair.[159]

Strains of *Escherichia coli* with null mutations in *sodAsodB*, the genes encoding superoxide dismutase, are sensitive to heating aerobically at 48°C, whereas the same stress applied to the parent strain had negligible effect.[15] This effect was not seen at 55°C, suggesting that at higher temperatures direct thermolability of other cell components overrides the effect of superoxide radicals. The metabolic flux of superoxide can vary widely depending on the metabolic substrates used as a source of electrons and the pathway of electron transport.[80] It is possible that metabolic imbalance or disorganization of the electron transport chain in damaged membranes could lead to increased production of superoxide, with lethal consequences. This has not been tested directly, but preliminary evidence has been obtained, using chemiluminescent probes of a burst of free radical production in *E. coli* following heat, osmotic, and ethanol shock.[2]

15.3.9 Effects of Temperature on Recovery

The optimum temperature for recovery of injured cells is often below the optimum for growth.[17,111] Figure 15-2 shows that incubation temperatures between 5° and 40°C had no effect on the plating efficiency of uninjured cells, whereas injured cell exhibited an optimum for recovery between 20° and 25°C. Incubating plates outside this range could reduce viable counts of injured cells by up to 500-fold. The reasons for this are not clear and are likely to involve a balance between the relative rates of repair processes and rates of degenerative changes leading to death in injured cells.

15.3.10 Metabolic Requirements for Repair of Injury

The repair of sublethal injury can be followed by using the differential plating method. After exposure to an injurious treatment, cells are incubated in broth and plated at intervals on an optimum medium to determine the total number of viable cells, and on a restrictive medium (eg, one containing bile salts or sodium chloride) that allows growth only of uninjured cells. The difference between the two counts gives the proportion of injured cells, and completion of repair is indicated when cells have regained ability to grow on the restrictive medium (Figure 15-3).

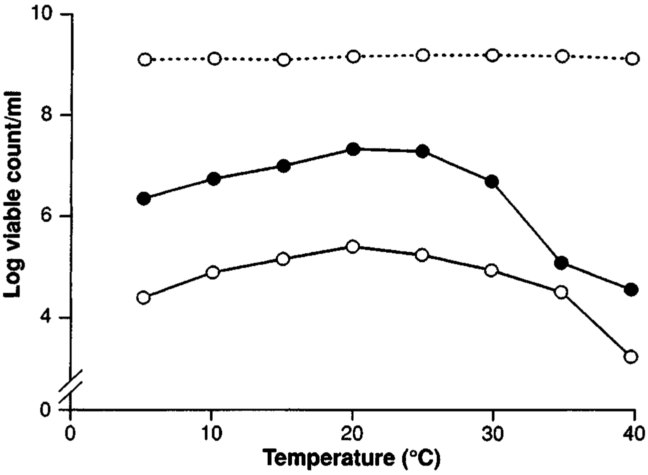

Figure 15-2 Effect of Temperature on Recovery of Heat-Injured *Listeria monocytogenes*. Viable counts of unheated cells (---O---); cells heated at 60°C for 10 min (●) or 20 min (O). *Source:* Reprinted with permission from B.M. Mackey et al., Recovery of Heat-Injured *Listeria Monocytogenes*, *International Journal of Food Microbiology*, Vol. 22, pp. 227–237, © 1994, Elsevier Applied Science.

The metabolic requirements for repair of injury have been studied by measuring the incorporation of radiolabeled precursors into cell components in the lag preceding multiplication or by examining the effect of metabolic inhibitors on the repair process. Tabulated summaries of the biosynthetic requirements for repair were provided by Tomlins and Ordal,[181] Mackey,[106] and Mossel and Corry,[120] and examples for *Salmonella* species are shown in Table 15-2. It is evident that biosynthetic requirements for repair vary between different stress treatments and can also vary for the same type of stress under different conditions (eg, chilling in water versus broth).

15.4 VIABLE BUT NONCULTURABLE CELLS

15.4.1 Characteristics of Viable but Nonculturable Cells

Recent studies, in which ribosomal RNA gene sequences are amplified by PCR directly from natural environments without first culturing the organisms, have amply demonstrated that a large proportion of bacteria present in the oceans, hot springs, and other ecological niches do not grow on standard laboratory media.[131] It is supposed that these so-far uncultured cells require special factors to permit growth, or are inhibited by the media used in attempts to isolate them. Earlier studies showed that the number of cells that could be cultured from marine or soil samples represented only a small fraction of the total that could be detected microscopically. It was suggested that bacteria in these environments spend much of their existence in a state of metabolic stasis or dormancy interspersed by short periods of growth.[171] It was further supposed that the dormant fraction was identical to the nonculturable fraction, although some recent studies have suggested that up to 50% of nonculturable cells in marine environments are not dormant and can be shown to be capable of multiplication in seawater but not on rich media.[31,161] The literature on dormancy of nonsporulating bacteria has been reviewed by Kaprelyants et al.[86] and Roszak and Colwell.[155]

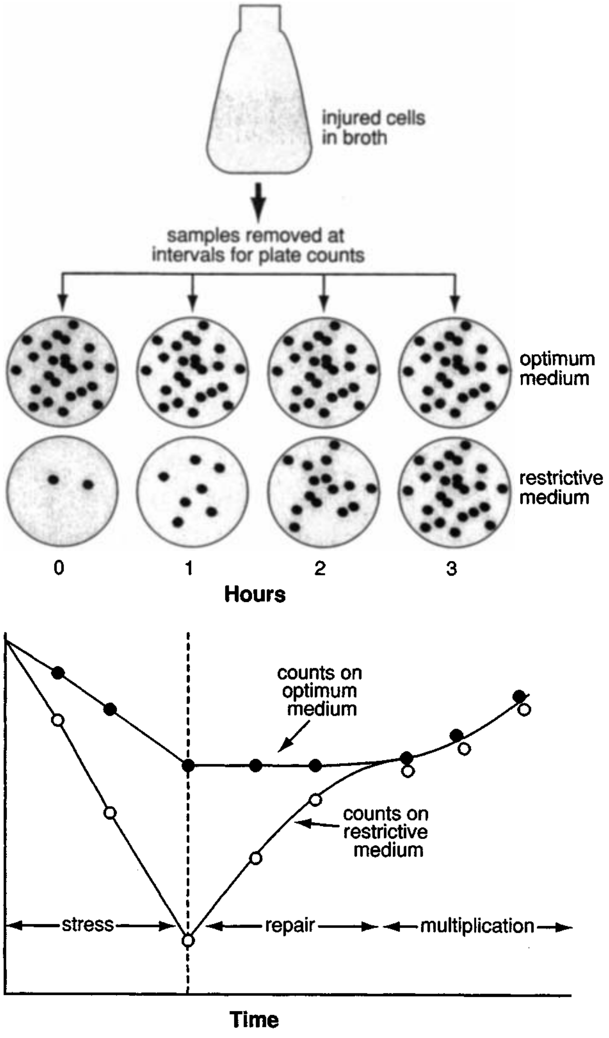

Figure 15-3 Method of Following Repair of Injury Using the Differential Plating Method.

In the present context, the term viable but nonculturable (VBNC) is applied in a more restricted sense to describe what is believed to be a temporary loss of culturability in bacteria that can normally be cultivated with ease. The term was first used by Colwell's group in 1982 to describe a phenomenon in *Escherichia coli* and *Vibrio cholerae* in which organisms that were incubated in salt water microcosms lost their ability to grow on nutrient agar plates but remained metabolically active over long periods.[198] There is no generally agreed definition of the VBNC state and in common usage it is rather loosely applied to (1) organisms that fail to grow on nutrient nonselective media that normally support their growth but which retain cellular metabolic activity measured in one of several different tests (see Section 15.4.2) and (2) organisms that become nonculturable but can regain the capacity to multiply on their normal growth media following a suitable resuscitation treatment. It should be noted that dormancy is defined simply as a state of rest or metabolic quiescence in which the phenotypic development of an organism is interrupted.[86,177] Therefore, dormancy is not necessarily associated with nonculturability and vice versa. Nevertheless, entry into a VBNC state in vegetative cells is often viewed as being analogous to spore formation in which cells become dormant as a means of surviving adverse conditions.

Barer[11,12] pointed out that since viability can only be definitely established by showing that cells can multiply, the term viable but nonculturable is in fact an oxymoron. An alternative terminology is suggested below (see Section 15.4.4) but, in the absence of a more precise agreed alternative, the term VBNC,

Table 15-2 Metabolic Requirements for Repair of Sublethal Injury in *Salmonella* Species

*+, synthesis required; 0, synthesis not required; ND, not determined.

as commonly used in the literature, will be retained in this discussion for convenience.

The VBNC state has been reported in many genera, mainly of Gram-negative organisms but including the Gram-positive *Micrococcus luteus, Listeria monocytogenes*, and *Enterococcus faecalis*. The most studied organisms have been *Escherichia coli, Vibrio cholerae, Vibrio vulnificus, Legionella pneumophila, Campylobacter jejuni, Salmonella enteritidis*, and *Micrococcus luteus*.[12,116] In most cases, the inducing stress is starvation in fresh or seawater, but VBNC cells have also been reported in response to biocide treatment, osmotic stress, exposure to sunlight, oxidative stress, aerosolization, and survival in soil. The nature of the VBNC state will be discussed below (see Section 15.4.3), but it is first worth summarizing the types of evidence on which the existence of the state is based.

15.4.2 Evidence for the VBNC State in Organisms That Can Normally Be Cultured

Epidemiological Evidence

Several ecological studies suggest that viable cells of pathogenic bacteria may be more numerous in aquatic environments than are detected by culture methods. In areas of the world where cholera is endemic, the isolation of *Vibrio cholerae* from water samples shows distinct biyearly peaks. At other times of the year, *V. cholerae* cannot be detected by culture methods but cases of cholera still occur. In contrast to the fluctuating pattern obtained by conventional culture methods, when water samples are examined using fluorescent antibody techniques, *V. cholerae* can be detected throughout the year. A similar seasonality is observed with *V. vulnificus*, which apparently disappears from coastal waters of the Northeast United States between October and June when the temperature drops to below 10°C. Estimates of the number of *V. fischeri* cells in marine samples based on plate counts were about 100 times lower than those based on quantitative DNA hybridization or ability to colonize the light organ of baby squid.[97] Plate counts also apparently underestimate numbers of *Legionella pneumophila* in tap water because fluorescent antibody tests indicated the presence of the organism in winter when none were detected by culture methods.[35] The evidence from epidemiology is of course circumstantial, and the detection of cells by nucleic acid or antibody-based methods does not prove that viable cells exist where none can be detected by culture methods. Nonetheless, these studies would be consistent with the existence of a VBNC state in natural environments.

Direct Indicators of Viability

Detection of metabolic activity at the single cell level and/or possession of an intact cell membrane is often taken as presumptive evidence of viability in nonculturable cells. The techniques listed in Table 15-3 have been applied to populations of organisms or, using fluorescence microscopy or flow cytometry, to single cells.[12,85,141,155] These techniques have shown that nonculturable cells can exhibit many properties associated with living cells including electron transport activity, maintenance of a membrane potential, induced enzyme synthesis, and ability to receive and express plasmids by conjugation.[6,128,140]

The direct viable count (DVC) method of Kogure[93] is one of the most common criteria of viability in studies of the VBNC state. In this test, cells that can elongate when incubated in medium containing yeast extract and an inhibitor of DNA synthesis are considered to be alive. Roszak et al.[156] found that plate counts of *Salmonella enteritidis* in river water declined to zero within 3 days whereas the ability of cells to respond in the Kogure DVC persisted for up to 60 days. It was concluded that cells had entered a dormant state. The persistence of a DVC response in nonculturable cells is very variable and, in some cases, the DVC can decline as rapidly as culturability.[24]

Organisms that have been killed by radiation retain extensive metabolic capacity including the ability to synthesize protein and to support propagation of bacteriophage. Similarly, *minicells* that lack DNA and are incapable of replication would give a positive response in many of the direct viability tests. The presence or absence of detectable metabolic activity is therefore not an unequivocal indicator of viability.

Resuscitation In Vitro

The most convincing verification of the VBNC state is to demonstrate loss and recovery of culturability under controlled conditions in the laboratory. The best characterized resuscitation system for Gram-negative bacteria has been that employing the marine pathogen *Vibrio vulnificus*.[126] When grown in artificial seawater and then chilled from a temperature of 22°C to around 10°C, the cells change in morphology from rod to coccoid shape and rapidly become nonculturable, but direct viable counts remain high. When the nonculturable population is warmed to 20°C, there is a rapid increase in plate counts accompanied by a reversal of the morphological change.

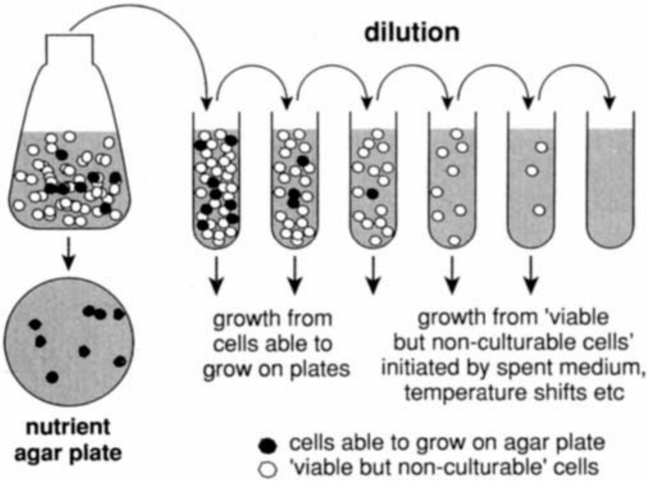
Table 15-3 Some Indicators of Single Cell Metabolic Activity

Function Measured	*Example of Method*
Membrane potential	Active uptake of Rhodamine 123 Exclusion of bis-oxonol
Membrane integrity	Exclusion of propidium iodide
Electron transport activity/generation of reducing power	Reduction of tetrazolium salts
DNA synthesis	Incorporation of radiolabeled thymidine
Protein synthesis	Incorporation of radiolabeled amino acid
Enzyme activity	Hydrolysis of fluorescein diacetate or derivatives by nonspecific esterases Fluorogenic ß-galactosidase assay
Intracellular pH	pH-dependent fluorescence spectrum of carboxyfluorescein succinimidyl ester
Coordinated macromolecular synthesis	Cell elongation in the presence of DNA gyrase inhibitors Induced enzyme synthesis

This process may represent resuscitation of VBNC cells to full viability, but an alternative explanation is that the increase in viable number is caused by multiplication of residual culturable cells. In some experiments, resuscitation was dependent on culture volume (and therefore the probability of there being a culturable cell present), and seawater was shown to support cell multiplication.[189,191] Similar conclusions were drawn from experiments with the eel pathogen *V. vulnificus* biotype 2[21] and with *V. cholerae*[146] but, in later experiments, resuscitation of *V. vulnificus* present in artificial seawater was possible from samples containing less than 0.0001 cfu.[192] The probability that normally culturable cells were responsible for the increase in viable count was therefore extremely low in this instance.

Much of the uncertainty of resuscitation experiments could be removed by appropriate experimental design using a most probable number (MPN) technique (Figure 15-4). Suspensions of bacteria believed to contain VBNC cells are serially diluted in a liquid medium before being incubated under conditions that will allow resuscitation to occur. Cells that can initially grow on plates are diluted out by this procedure so any growth in tubes at greater dilutions must come from resuscitation of VBNC cells. By performing serial dilutions in replicate (eg, five replicates), the MPN can be calculated and compared with the plate count to give the proportion of VBNC cells in the population.

The Gram-positive organism *Micrococcus luteus* becomes dormant and also nonculturable when maintained for several months in a spent culture medium but can be resuscitated by incubation in fresh medium containing filter-sterilized culture fluid obtained from a culture in late exponential phase. The number of dormant viable cells, estimated by MPN counts in medium containing culture filtrate, was shown to be about 10,000 times greater than the number of cells able to grow on plates of normal growth medium.[87,186] However, similar MPN experiments with *V. vulnificus* employing a range of nutrient and dilute media and spent broth were unsuccessful at resuscitating cells from a nonculturable state.[189] Similarly, the MPN method demonstrated that the apparent resuscitation of *V. parahaemolyticus* cells after a temperature upshift represented growth of a few surviving cells.[81] When spent broth cultures of *C. jejuni* consisting predominantly of coccoid cells are sparged with a microaerophilic gas mixture there is a rapid increase in viable numbers accompanied by a change from a predominantly coccoid to vibrioid morphology. Application of the MPN approach showed that this could be largely explained by multiplication of residual culturable cells.[26] However, plate counts of aged cultures under supposedly optimum microaerophilic conditions underestimated the viable count by up to 20-fold, indicating that a fraction of survi-



dilution
nutrient agar plate
growth from cells able to grow on plates
growth from 'viable but non-culturable cells' initiated by spent medium, temperature shifts etc
● cells able to grow on agar plate
○ 'viable but non-culturable' cells

Figure 15-4 Use of the MPN Approach To Distinguish Resuscitation from Multiplication.

vors were in an injured or latent state, though the numbers of such cells were much less than in starved *M. luteus*.[26]

Recovery of *Legionella pneumophila* from water samples that initially contained no detectable culturable cells was achieved by a mild heat-shock treatment.[35] In a different system, cells of *L. pneumophila* that had been nonculturable for 55 days in tap water did not respond in the Kogure DVC but were recovered by co-culture with *Acanthamoeba castellani*.[172] In this study, a heat shock had a detrimental effect on reactivation. Several protozoan species support the growth of *L. pneumophila,* and it will be interesting to discover the factors that promote recovery of starved cells. However, as with other resuscitation studies, it will be necessary to use the MPN approach to determine what fraction of remaining cells is actually capable of being resuscitated.

Pathogenicity of VBNC Cells

Colwell et al.[36] first reported that cells of *V. cholerae* rendered nonculturable by incubation in estuarine water microcosms retained virulence when tested in rabbit ligated ileal loop assays, and later reported that the VBNC form of a vaccine strain could revert to culturability when fed to human volunteers.[37] Evidence for virulence of VBNC cells has been produced for several other species but in some cases the evidence is contradictory (Table 15-4). For example, Jones et al.[83] were able to recover culturable cells of *C. jejuni* from the VBNC state following feeding to suckling mice whereas Medema et al.[117] and Beumer et al.[18] were unable to demonstrate reversion, colonization, or infection in a variety of different systems and Fearnley et al.[50,51] found that the ability to colonize chicks was lost before cells became nonculturable (Table 15-4). The reasons for these discrepancies are not known but may be related to the method of producing VBNC cells and the length of time they have been in the VBNC state. Feeding and infectivity studies have been criticized for the same reasons as *in vitro* resuscitation studies on the grounds that infection could have been due to culturable cells that were undetected because of sampling errors in the viable count procedures. This argument requires either that appreciable numbers of cells were missed by the viable count method or that the number of surviving cells in the inoculum, and hence the infective dose, is very low. These objections might be overcome by more quantitative

Table 15-4 Infectivity or Virulence of VBNC Cells

Organism	*Inducing Treatment*	*Assay System*	*Result*	*Reference*
Vibrio vulnificus	Temperature downshift	Injection into mice	+	129
Vibrio cholerae	Estuarine water	Rabbit ligated ileal loop	+	36
Vibrio cholerae (vaccine strain)	Phosphate buffered saline	Human volunteers	+	37
Legionella pneumophila	Tap water	Injection into embryonated eggs	+	79
Campylobacter jejuni	Pond water	Suckling mice	+	83
Campylobacter jejuni	Phosphate buffered saline	Chick colonization	+	174
Campylobacter jejuni	Freeze thaw	Rat ileal loop	+	159
Campylobacter jejuni	Reservoir water	Inoculation into embryonated eggs	–	117
		Chick colonization	–	
Campylobacter jejuni	Distilled water or freeze thaw	Chick colonization	–	50, 51
Campylobacter jejuni	0.85% saline	Feeding to: mice, rabbits, human volunteers	–	18
Helicobacter pylori	20 days in broth	Intragastric inoculation into mice	+	34
Aeromonas salmonicida	Seawater	Infection of fish	–	154
Shigella dysenteriae	Distilled water	Detection of Shiga toxin	+	144
		Adherence to Henle cells	+	
		Invasion of Henle cells	–	
Enterotoxigenic *Escherichia coli*	Seawater/sunlight	Rabbit intestinal loop	+	139
		ELISA for enterotoxin	+	

data although this is difficult because of the inherent variability of infective doses. Interpretation of results from model systems is also complicated by the multifactorial nature of bacterial virulence and, in some trials, VBNC cells responded in some but not all tests of virulence (Table 15-4). It would be helpful in these cases to compare the responses of VBNC cells with those of similar numbers of unequivocally dead cells (eg, killed by gamma-irradiation), but this is seldom done. Thus, although several studies have concluded that VBNC cells remain virulent and have taken care to avoid spurious results from viable cells being present, this conclusion remains controversial. The implications for public health of VBNC cells remaining infective are serious but, because of the conflicting experimental results, the pathogenicity of VBNC cells cannot yet be regarded as firmly established and the relevance to human infection of the VBNC state remains uncertain.

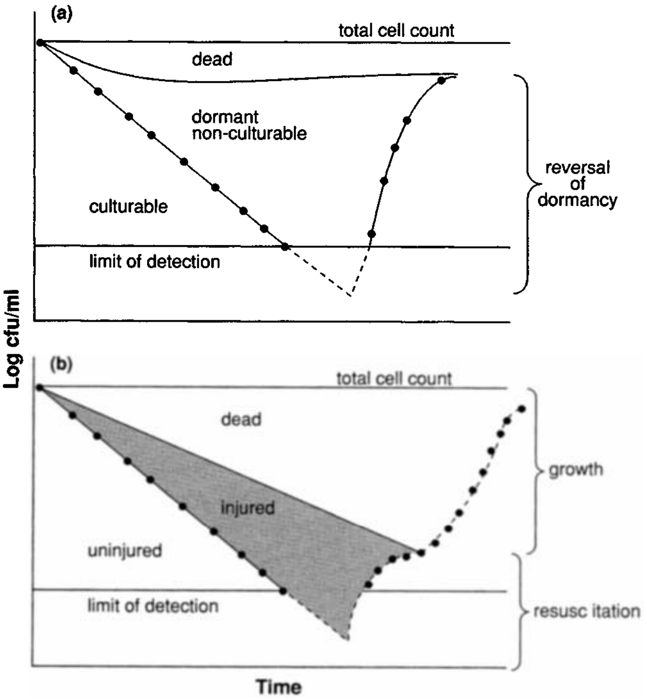


Figure 15-5 Two Interpretations of the Increase in Viable Numbers Seen during Resuscitation of VBNC Cells. **A**, The increase in viable count is due to a reversal of dormancy in a large proportion of the total cell population. **B**, The increase in viable count is due to repair of injury in a relatively small fraction of the population followed by multiplication. At the start of resuscitation, the number of uninjured cells is below the detection limit.

15.4.3 The Nature of the VBNC State

The VBNC state is commonly interpreted as a survival mechanism wherein cells become metabolically quiescent or dormant in response to adverse conditions. This is seen as being analogous to spore formation and is presumed to be a genetically programmed process. According to the dormancy hypothesis, cells can persist for long periods in the VBNC state, and the large increase in viable numbers that occurs during resuscitation is mainly or entirely due to the reversal of dormancy. This is shown schematically in Figure 15-5A. In *Micrococcus luteus*, a 16 to 17 kD_a protein has been identified in spent medium that is needed to reverse the dormant state.[123] Dormant bacterial endospores also require specific signals (germinants) to become active but, in this case, the signal molecules originate from the environment rather than other organisms. "Wake up" factors have not yet been identified for other VBNC cells although growth of the eukaryotic microbes *Tetrahymena* from very small inocula was specifically stimulated by 8-bromo cyclic GMP, a signal molecule present in spent medium.[145] The lag phase of starved ammonia oxidizing bacteria following resupply of ammonia was dramatically reduced by a homoserine lactone.[13]

There are several complicating factors in applying the dormancy hypothesis to all VBNC conditions: (1) one class of VBNC cells is in fact defined by its ability to display appreciable metabolic activity and thus cannot also be considered dormant; (2) the VBNC state may arise in response to a sudden stress such as aerosolization[69] that would preclude any cellular differentiation process; and (3) in at least two published papers, the nonculturable phenotype was observed in suspensions that were multiplying at the time of sampling, as judged from an increasing total count or DVC.[122,132]

An alternative explanation is that stressed cells are nonculturable because they are injured or otherwise in a physiological state that sensitizes cells to dilution protocols or components of recovery media, or which results in metabolic imbalance and death when cells are placed on nutrient agar plates. According to this view there could be many different causes of temporary nonculturability. Weichart and Kjelleberg[189] found that chilled cells of *V. vulnificus* recovered better on soft agar (0.2% to 0.8%) plates than on ordinary agar and Whitesides and Oliver[192] showed that Heart Infusion broth inhibited resuscitation of *V. vulnificus* (although it was not lethal during a 12-hour period of exposure). Mukamolova et al.[122] concluded that the filtered supernatant from a growing culture of *M. luteus* stimulated resuscitation of starved cells by overcoming the activity of an antibacterial factor, produced during resuscitation, that caused self-poisoning. Temporary nonculturability was induced in exponential phase *E. coli* as a result of osmotic stress but could be reversed by betain[157]; and in *L. monocytogenes*, a similar temporary loss of colony-forming ability in osmotically stressed cells was correlated with membrane damage detected by ethidium bromide staining.[153] The role of oxidative stress in the recovery of stressed cells was emphasized above and could also be important in the VBNC phenomenon.

The shape of the resuscitation curves in published data is sometimes characterized by an initial rapid increase in viable numbers followed by a plateau then a second increase.[130] This would be consistent with an initial phase of resuscitation followed by a lag preceding multiplication (Figure 15-5B). The period during which it is possible to resuscitate cells beyond the point at which plate counts become zero, would thus depend on the ratio of injured to uninjured cells and the rates of decline of both.

A third possibility is that, in some cases at least, the putative VBNC cells are actually dead (incapable of multiplication under any conditions) but retain metabolic capacity for a period that depends on the relative rates of decay of a function essential for multiplication and of other cell functions. Weichart et al.[190] postulated that there are two phases in formation of nonculturable cells of *V. vulnificus*: the first involves loss of culturability with maintenance of cellular integrity (and possibly viability) while the second is typified by gradual degradation and loss of nucleic acids. Boucher et al.[25] showed that nonculturable cells of *Campylobacter jejuni* could reduce tetrazolium salts but that the ability to do so declined with time and concluded this was a gradual degenerative process leading to cell lysis. In *C. jejuni* conversion to the coccoid form was not prevented by inhibitors of protein or RNA synthesis or by irradiating the cells, demonstrating that the process was not an active one.[68] Coccoid cell formation in *Helicobacter pylori* was accompanied by a reduction in the amount and integrity of RNA and DNA and was also not prevented by inhibitors of protein or RNA synthesis. Nonculturability occurred while 50% of cells were still in the bacillary form, and it was concluded that the coccoid form of *H. pylori* is a morphological manifestation of cell death.[94]

There is an increasing tendency in the literature to label all physically intact cells that cannot be recovered, but which exhibit metabolic activity or can be detected by gene probe methods, as VBNC. It is now very well established that such cells retain many of the properties of living cells for a long time after culturability has been lost, but the evidence that they also remain capable of reproduction is often weak. At the time of writing, resuscitation of VBNC cells has been unequivocally demonstrated in relatively few cases, and in only one instance (*M. luteus*) has it been shown that a large proportion of the total cell population is capable of being resuscitated. In view of the large body of circumstantial evidence that a VBNC state may exist in many organisms, and the wide implications that this would have for monitoring and safety, there is an urgent need for better designed resuscitation experiments to establish the true extent and significance of the phenomenon. There may be many quite separate reasons for temporary nonculturability, and it is essential to understand the physiological mechanisms involved and the properties, including resistance, of VBNC cells.

15.4.4 Terminology

If one accepts that the definition of a viable bacterial cell is one that is capable of multiplying under suitable conditions, then there is no justification for labeling cells as viable unless there is good evidence that they can indeed multiply. A term such as (metabolically) active but nonculturable (ABNC) would be a nonprejudicial descriptor for organisms currently described as VBNC on the basis of their response in the Kogure DVC, ability to reduce tetrazolium dyes or other similar tests. In cases where resuscitation, and hence viability, has been demonstrated, but the cause of the temporary inability to grow on agar plates is not known, cells could be described as *fastidious* (or to have entered a fastidious state), a generic term describing cells that require special conditions to initiate growth, whether as a result of dormancy, metabolic imbalance, injury, or any other reason. An active but nonculturable (ABNC) cell could thus be dead, or alive but fastidious. Once the basis of nonculturability is discovered, more specific descriptors of the cell's physiological state could be used.

15.5 SPORE INJURY

15.5.1 The Occurrence of Spore Injury

The pioneering work of Bigelow and Esty in 1920[19] was the first major work on thermal inactivation of spore formers and this was followed in 1922 by the definitive work of Esty and Meyer on thermal destruction of *Clostridium botulinum*.[49] These early quantitative studies enabled the lethal effects of different time/temperature combinations to be calculated and laid the foundations for safe processing of canned foods. It was soon discovered that the type of medium and incubation conditions used for recovery after heating had a pronounced effect on the apparent number of spores that survived the process. This had obvious implications for thermal processing calculations and stimulated much work on optimizing recovery conditions and on understanding the reasons why some media performed better than others.[40,195] General aspects of spore injury and recovery were discussed by Gould[58] and Foegeding and Busta.[52] Other reviews deal with heat injury,[1,11] chemically induced injury,[23] and spore DNA damage and repair.[164] Practical aspects of the recovery of spores damaged by heat, ionizing radiation, and ethylene oxide were reviewed by Roberts.[151]

Typical symptoms of spore injury include increased germination lag and microlag, altered nutritional requirements, sensitivity to recovery on different batches of media, altered optimum temperatures for recovery, enhanced recovery in the presence of starch or activated charcoal, recovery more markedly influenced by gas atmosphere or redox potential, and sensitivity to sodium chloride and other food preservatives and antibiotics. Injured spores thus resemble injured vegetative cells in being more fastidious in their growth requirements than uninjured forms. However, some forms of injury are associated with specific spore structures and are thus unique to spores. Also, the dehydrated state of the core can affect the conformation of macromolecules and hence the nature of damage caused by deleterious agents. This is especially true of DNA and the damage caused by UV light (see below). A further difference is that the spore is metabolically inactive, and sublethal injury is only detectable during germination or outgrowth. Table 15-5 summarizes the symptoms and possible mechanisms of spore injury.

15.5.2 Germination Systems

In some species of *Clostridium* and *Bacillus*, the germination system is apparently more sensitive to

Table 15-5 Sublethal Injury of Bacterial Spores

Treatment	*Manifestation of Injury*	*Proposed Mechanism/Site of Injury*
Heat	Requirement for non-nutrient germinants (lysozyme, Ca-DPA)	Inactivation of germination system
Heat	Altered optimum temperature for recovery	(a) Selective activation/inactivation of germination systems having different temperature optima (b) Need for low metabolic rate to allow coordination of biosynthesis while repairing damage during outgrowth
Heat	Altered nutritional requirements	(a) Stimulation of secondary germination system (b) DNA damage and increased frequency of auxotrophic mutants
Heat, ionizing radiation	Increased sensitivity to salt, nitrite, and some surface active compounds and antibiotics	(a) Damage to spore protoplast membrane (b) Sensitivity of DNA repair enzymes to salt
Ionizing radiation	Loss of heat resistance	Damage to spore cortex
Treatment with alkali and/or reducing agents	Increased sensitivity to iodine, halogen-releasing compounds, chloroform, and, depending on species, hydrogen peroxide, ethanol, and glutaraldehyde	Removal of, or damage to, spore coat
Heat	Increase in germination lag and microlag	Decrease in specific activity of cortex lytic enzyme
Acid	Dormancy Loss of heat resistance	Removal of cations from key sites

heat than the spore as a whole. Spores that have been heat damaged fail to respond to normal germinants and remain dormant unless the germination system is bypassed by exogenous germinants such as lysozyme[33] or calcium dipicolinate.[47]

The beneficial effect of lysozyme on recovery of heat-stressed spores can be very large for some species.[102] For example, the number of survivors recovered after heating spores of nonproteolytic strains of *C. botulinum* at 85°C for 10 minutes was increased by factors of 10^3 to 10^6 if media contained as little as 625 units lysozyme ml^{-1}.[134] Survivor curves obtained using lysozyme-containing recovery media were biphasic, the initial decline representing inactivation of the fraction of spores that were impermeable to lysozyme (Figure 15-6). If spores were treated with alkaline thioglycollate to disrupt the spore coat and render all spores permeable to lysozyme, the initial rapid decline disappeared and linear curves were obtained with the same slope as the "tail" region of biphasic curves. The difference in slope of the two parts of the biphasic curve presumably represents the different rates of inactivation of the germination system and other targets of heat inactivation. On this basis, the germination system of *C. botulinum* 17B is at least 100 times more heat sensitive than other (unknown) critical targets of heat inactivation. Recovery of proteolytic strains of *C. botulinum* is only marginally improved, if at all, by lysozyme, so their germination systems are apparently more effectively protected against heat. The persistence of an active L-alanine germination system in heat-killed spores of *Bacillus terminalis*, was described by Roberts.[151] A shift in the optimum temperature for recovery of *B. subtilis* A from 45°C to 32°C was attributed to inactivation of the normal L-alanine germination system accompanied by activation of a previously latent system active at lower temperatures.[1]

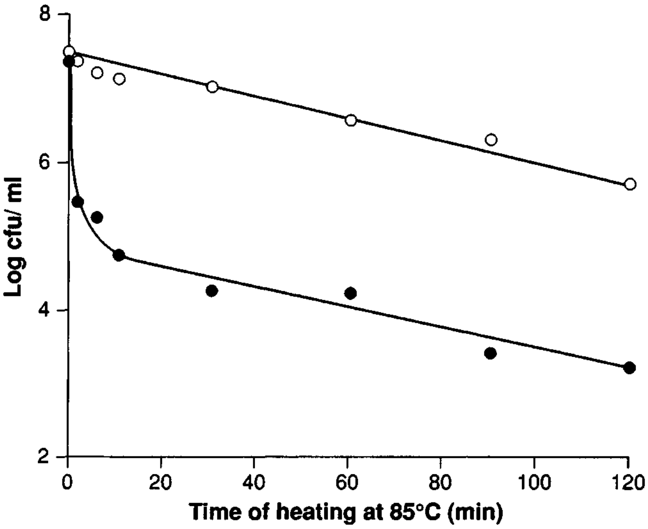

Figure 15-6 The Effect of Treatment of Heated Spores of Nonproteolytic *Clostridium botulinum* Strain 17B with Alkaline Thioglycollate, prior to Plating on Medium containing Lysozyme. 15.5.3 Spore Membranes

The increased sensitivity to curing salts, detergents, and antibiotics in spores damaged by heat or ionizing radiation is attributed to damage to the cortical and/or protoplast membranes.[1] Ions or charged molecules do not readily pass across lipid membranes and the greater sensitivity of spores to NaCl, sodium nitrite, and H^+ ions would be consistent with membrane damage sustained in the spore but manifest during germination and outgrowth. Increased sensitivity to antibiotics and detergents has also been attributed to membrane damage because sensitivity was associated with osmotic fragility, and could be repaired in the absence of new macromolecular synthesis. The inhibitory effects of antibiotics and salts were not additive, suggesting that sensitivity to each resulted from damage to a common target site believed to be the membrane. Spores treated with glutaraldehyde, iodine solutions, or chlorine-releasing agents became sensitized to anionic or cationic surfactants and polymyxin. These agents are known to cause damage to spore integuments but the precise site of injury responsible for sensitivity is not yet known. Repair and recovery of resistance occurred after germination at the outgrowth stage.[193,194] Inconsistent or poor recovery of damaged spores on rich nutrient media is usually attributed to the presence of unspecified inhibitors, which can sometimes be removed by adsorption to the amylose component of starch or by activated charcoal. Traces of unsaturated fatty acids, which inhibit germination, are believed to be responsible for inhibition in some cases but the identity of the inhibitors is generally not known. Whether or not spore membrane damage accounts for increased sensitivity is also not clear.

15.5.4 Spore Coat

Damage to the proteinaceous spore coat results in sensitivity to peroxide, solvents, and biocides, but conflicting results and differences between strains have been reported.[23] This form of damage is associated with chemical treatments with alkali, reducing agents, or denaturants rather than the physical treatment used in food processing.

15.5.5 Cortex

Glutaraldehyde can induce a form of sublethal injury in which spores cannot germinate unless first treated with alkali.[41] It is believed that the bifunctional agent glutaraldehyde cross-links amino groups of the cortex, producing a tough sealed structure that prevents normal germination.

Sublethal damage to the cortex is also produced by ionizing radiation. In this case, the observed effect is a decrease in heat resistance resulting from a loss of ability to maintain the dehydrated state of the core. Heating irradiated spores at reduced water activity restored heat resistance.[56] High concentrations of nitrite under acidic conditions can induce germination-like changes in spores. This is caused by hydrolysis of the cortical peptidoglycan by nitrous acid.[58]

15.5.6 DNA

Bacterial spores have been reported to survive for hundreds or, in some cases, thousands of years. The DNA must therefore be in a state that is resistant to the degradative processes—principally hydrolytic and oxidative—that would otherwise destroy it over these time periods, even at moderate environmental temperatures.[99] A large body of evidence has shown that the small acid-soluble proteins (SASPs) that saturate the spore protoplast play a major role in protecting DNA against heat, oxidative attack, freeze drying, and UV radiation.[165] These proteins bind to DNA and protect it against the depurination and strand-breakage events associated with heat or oxidative attack. When SASPs bind to DNA they alter its conformation to a form having some similarities to the A form seen in dehydrated DNA fibers. One consequence is that the photoproduct arising when spores are irradiated with UV light differs from that in vegetative cells (thyminyl thymine adduct, or spore photoproduct, rather than cyclobutane dimer). The spore photoproduct (SP) is potentially lethal, but the lesion is corrected during germination and outgrowth by two repair pathways, nucleotide excision repair, and an SP-specific enzyme called SP lyase. These pathways, however, were not efficient at repairing damage caused by solar radiation.[199]

When spores are heated at very high temperatures (130°–155°C), particularly in the dry state, the protective mechanisms are no longer adequate to prevent depurination damage to DNA. The surviving spore population contains a high proportion of auxotrophic and other mutants, accounting for the altered growth requirements of spores surviving ultrahigh temperature processes.[200] High mutation frequencies are not observed in survivors heated in water at lower temperatures or those exposed to hydrogen peroxide. However, mutants lacking SASPs do show high mutation levels given similar treatment, indicating that the SASPs normally protect DNA against this form of sublethal damage.

15.6 RECOVERY OF INJURED SPORES

Unfortunately, it is not possible to make general recommendations suitable for all types of spore injury or all species, but inspection of the literature will usually yield media and incubation conditions appropriate for the major foodborne spore formers.[82] For recovery of severely damaged spores, additives such as blood, charcoal, pea infusion, or starch to neutralize traces of inhibitors present in the media may be necessary for maximum recovery. In general, media made from fresh infusions have proved better than those made from dehydrated ingredients. Injured anaerobes seem particularly sensitive to gas atmosphere and/or redox potential but the interactions between gas atmosphere and reducing agent can be complex, and in some cases, the simple expedient of pour plating and incubating anaerobically can give better recoveries rather than attempting to find optimum atmospheric conditions for surface-plated samples.[151] Bicarbonate is not germinative alone but at concentrations of 30 mM strongly stimulates germination of several species of clostridia, and may be an absolute requirement for some. Spores of bacilli are not normally affected. Addition of 0.1% bicarbonate to Reinforced Clostridial Agar increased the recovery of heat-damaged spores of *C. botulinum*, *C. sporogenes*, and *C. histolyticum* by between 4- and 130-fold.[151] The optimum temperature and pH for recovery of damaged spores may differ appreciably from the respective optima for growth but there are marked differences in results obtained by different workers depending on the species or strain of organism and the nature and severity of the damaging treatment.

Because germination microlag times vary within populations of injured spores, the apparent probabil-

Next Page

ity of survival will depend on the incubation time of recovery media. Similarly, the probability of growth in a product will depend not only on the absolute stochastic probability of spore survival but also on storage time and a factor associated with the statistical distribution of microlag times within surviving spores. Spoilage of food products by thermophilic anaerobes can sometimes occur after a delay of several months. Spore germination times can approximate to a log-normal or skewed log-normal distribution with the mean germination time and standard deviation depending on temperature.[20,59,152] The variation in microlag times within populations of *C. botulinum* would explain why time to toxin production becomes much more variable as inoculum size decreases. In predictive modeling studies of survival and growth of *C. botulinum,* it is normal to use extended incubation times of 3 to 6 months to allow for delayed spore germination. Information on the effect of type of treatment and its severity on the distribution of spore germination times would help refine such models.

15.7 RECOVERY OF INJURED VEGETATIVE CELLS

15.7.1 Choice of Recovery Medium

The most appropriate recovery medium can only be found by trial and error. In general, cells injured by physical or chemical treatments recover best on a rich medium containing blood, catalase, or pyruvate to circumvent problems of oxidative stress. Recent work has shown that strictly anaerobic conditions may be necessary for maximum recovery of heat-treated cells. Starved cells, especially those from marine or freshwater samples, may recover better on a medium containing low levels of nutrients.[53] In some instances, liquid media may give better recovery than solid, possibly because of inhibitors present in agar or desiccation effects. Some species such as *C. jejuni/coli* seem especially sensitive to the dryness of agar plates and a moist atmosphere is important in recovery. (For further information on the choice of recovery medium, see Chapter 62.)

15.7.2 Sample Handling

Sample preparation and dilution can injure delicate cells or kill those already injured. When cells are in the exponential phase of growth they are particularly susceptible to all forms of mild stress.[141] The effects of rapidly cooling growing cells to 0°–5°C can be lethal, but it is not generally appreciated that much smaller temperature shifts can injure exponentially growing cells.[104,107] Many of the commonly used buffers and physiological salts solutions are rather harmful to injured cells and many studies have concluded that diluents should include magnesium (5 mM) and/or peptone (0.1%) to protect susceptible cells.[121] Rapid rehydration of dried samples can be lethal. A slow reconstitution procedure doubled the number of *Salmonella*-positive samples when examining dried milk, egg yolk powder, and other dried foods.[185] The recovery of airborne bacteria was improved by including betaine in the sample diluent.[114]

15.7.3 Resuscitation

There are three general strategies for avoiding counting errors arising from the use of selective media: (1) avoid the use of selective media altogether, (2) formulate the medium to minimize any inhibitory effects on injured target organisms, and (3) perform a resuscitation treatment to allow repair of injury before inoculation on/into a selective medium.

An example of the first approach is the use of size selection with membrane filters to isolate campylobacters and other small microbes.[65] This technique depends on the ability of small vibrioid cells to pass through the 0.45 µm pores of a membrane filter placed on nonselective agar. When applied to stool samples of animals and humans this method allowed isolation of *C. upsaliensis* and other species that were initially overlooked because they were inhibited by the usual selective media.[90,101]

Another possibility is to use selective media that are not inhibitory to injured target organisms. Baird-Parker agar supports good recovery of *S. aureus* cells damaged by drying, freezing, or heating.[9] There are few other examples of such media, presumably because resistance to many selective agents (eg, bile salts, sodium chloride, triphenylmethane dyes, large hydrophobic antibiotics) depends on having intact cell membranes, and these are almost always a site of cellular injury. Mannitol egg yolk polymyxin agar for *B. cereus* and Skirrow's antibiotic blood agar for *Campylobacter* have also been reported to have minimal inhibitory effects though selectivity may be less as a consequence.[121]

Where inhibitory selective media cannot be avoided, resuscitation on solid or in liquid is needed. In addition to improving the sensitivity of detection methods, including a resuscitation step tends to improve consistency and to reduce variability between laboratories.[185] Solid medium repair is the method of choice where quantitative estimates of viable numbers are needed. This can be achieved by spreading cells on the surface of a nonselective agar medium and, after allowing for repair to occur, overlaying with a selective medium. A more satisfactory method is to incubate cells on a membrane filter on a nonselective medium before transferring the membrane filter to selective agar, as in the modified direct plate method for *Escherichia coli.*[73] The increase in count achieved by solid medium repair typically varies between 2- and 100-fold when enumerating stressed coliforms in food.[121,147]

In presence/absence tests designed to detect very low numbers of cells, as used with *Salmonella*, a pre-enrichment treatment in liquid medium for *ca.* 18 to 24 hours allows low numbers of cells to repair injury and also to multiply to levels that can be detected during the later stages of the procedures. Recent work has revealed wide differences in the ability of pre-enrichment broths to recover injured salmonellae. The number of cells recovered differed by as much as 1,000-fold between the worst and best media[173] (see also Chapter 62).

15.7.4 The Time Needed To Repair Injury

The time required for repair depends on the organism, the type and severity of injury, and the inhibitory nature of the selective agent. Figure 15-7 shows that lag times of *Salmonella typhimurium* injured by heat or gamma-radiation increased as the surviving fraction decreased, but the lag times of heat-injured cells after equivalent lethal treatments were much longer. The implication of these results is that lethal and sublethal injury occurred at different relative rates depending on the treatment. In the case of heat, there was presumably much more "collateral" damage to nonlethal targets before cells died. With gamma-radiation, which has a much more specific target, such damage was substantially less. A model of thermal injury was presented by Gould[60] in which heat is assumed to inactivate a key lethal target, while at the same time destroying many other targets present at higher copy numbers. Loss of the less-critical targets does not cause death until their numbers are reduced to very low numbers or the cell is subject to additional stress. A modified version of this model is shown in Figure 15-8. Critical and less-critical targets are present at different copy numbers per cell as before, but the probability of sustaining a "hit" is independent for each target and depends on the nature of the damaging treatment (heat, acid, radiation, etc). Lethal and sublethal events thus occur at random, but with a different probability for each. If the probability of a lethal event is much lower than that of a sublethal event, surviving cells will be severely damaged and will have long lag times. If the probabilities

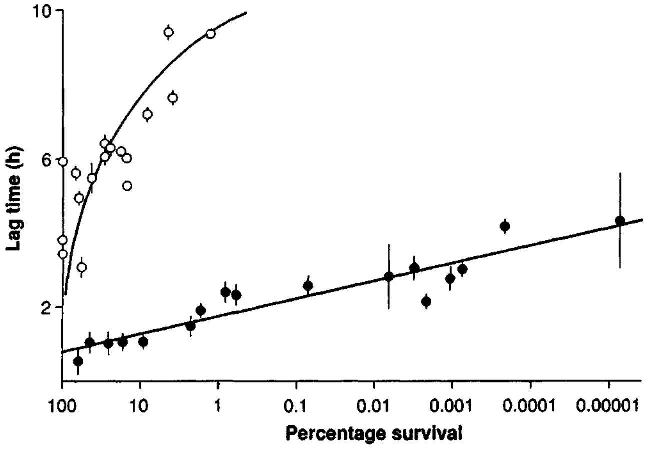

Figure 15-7 The Effect of Heat or Gamma-Radiation on the Duration of the Lag Phase of *Salmonella typhimurium*. Lag times were determined at different levels of survival following heating in 0.1 mol l^{-1} phosphate buffer pH 6.0 (○) or following gamma-irradiation from a ^{60}Co source (●). *Source:* Reprinted with permission from B.M. Mackey and C.M. Derrick, A Comparison of Solid and Liquid Media for Measuring the Sensitivity of Heat-Injured *Salmonella typhimurium* to Selenite and Tetrathionate Media and the Time Needed to Recover Resistance, *Journal of Applied Bacteriology*, Vol. 53, pp. 233–242, © 1982, Blackwell Science Ltd.

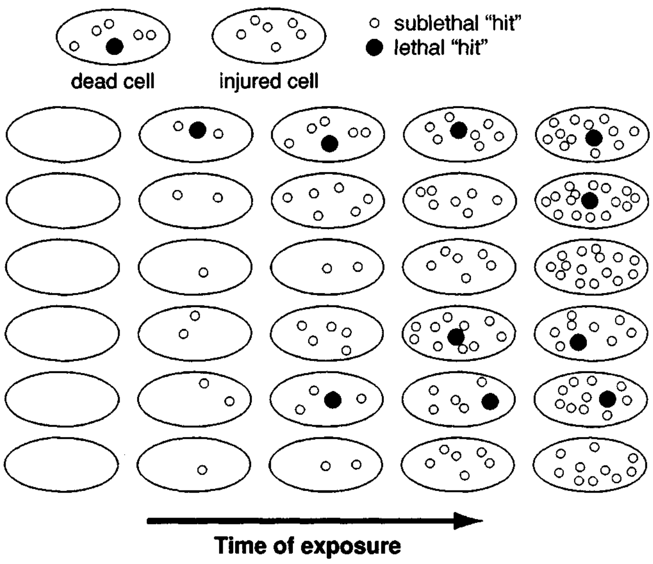

Figure 15-8 Random Accumulation of Lethal and Sublethal Injury in a Bacterial Population. *Source:* Copyright © 1989, G.W. Gould.

are similar, survivors will be less severely injured and lag times correspondingly shorter.

Measurements of repair times of cell populations using the differential plating method suggest that, under optimum conditions, injury caused by chilling, freezing, freeze drying, gamma-radiation, or acid is normally repaired within 4 to 5 hours and often within 1 to 2 hours. Mild heat injury can be repaired in about 5 hours under optimum conditions but cells with severe heat injury may require much longer times. *Enterococcus faecalis* needed up to 24 hours to recover resistance to tellurite after being heated at 60°C for 4 minutes.[133]

15.7.5 Heterogeneity within Injured Populations

The differential plating method gives an estimate of the "average" repair time of a population of cells and is therefore biased toward the fraction of cells in the population with the shortest individual lag times. These quick-repairing cells will multiply and mask the presence of cells having longer repair times. A mathematical treatment of the relationship between the lag time of a population, and the distribution of lag times of single cells within the population, was provided by Baranyi.[10] Pathogens in food may be present in low numbers and unevenly distributed. When estimating the risk of an injured cell recovering within a particular time, it is therefore important to understand the distribution of lag times within a population. The repair of single cells of *S. typhimurium* was monitored by spreading heat-injured cells on membrane filters, incubating these on nonselective agar to allow repair of injury and transferring at intervals to nutrient agar plates containing salt. This revealed that in a population having an "average" lag time of 9 hours, some cells required up to 14 hours to repair injury.[104] The distribution of lag or repair times may also be examined by progressively diluting a culture and measuring lag times in replicate inocula using an automated apparatus.[104] If the culture is diluted so that only 63% of replicate inocula will result in growth, then the average number of cells per inoculum is one. Use of this approach revealed a very wide distribution of lag times of single cells of heat-injured *S. typhimurium*, with many values in excess of 20 hours[173] (Figure 15-9). These observations have obvious implications for pre-enrichment methods intended to allow resuscitation and detection of low numbers of injured cells (see also Chapter 62).

15.7.6 The Relevance of Resuscitation to Newer Methods of Detection

A large number of alternative methods for detecting microbes are now available with test times as short as 30 minutes. Broadly, these methods are based either on detecting the physical presence of a cell (eg, gene probe or antibody-based methods) or on detecting metabolic activity (eg, electrochemical or dye-reduction methods). The role of resuscitation and/or pre-enrichment in this context is (1) to enable target organisms to increase to detectable levels or (2) to allow restoration of metabolic activity lost as a result of stress. Resuscitation would obviously play no role in the detection of preformed toxins or nucleic acids directly extracted from food.

Rapid methods are often inherently less sensitive than traditional culture methods where self-amplification (multiplication) of the target occurs. Even where a method is very sensitive, as with the polymerase chain reaction (PCR), its sensitivity in practice is limited by the problems of extracting the target analyte from the food matrix and presenting it to the endpoint detection system. With liquid samples concentration of target can be achieved by filtration but in more complex food matrices it is not possible to remove and concentrate very low numbers of cells. Direct extraction of DNA from cheese, coleslaw, and raw chicken followed by PCR allowed detection of 10^3–10^4 cfu of *Yersinia enterocolitica, Aerococcus viridans*, and *Listeria monocytogenes* per g.[45] To increase sensitivity, therefore, requires pre-enrichment, as with conventional methods. However, because gene probe or antibody-based methods are highly specific, it should be possible in principle to examine pre-enrichment broths directly, without the need for selective enrichment. Many protocols employing nonselective enrichment followed by PCR or fluorescent antibodies have now been reported[96,100,137,196] but there appear to be few studies on the effect of cell injury on the population dynamics in these systems and on the resuscitation times and conditions needed to achieve detectable levels.

Gene probe or antibody-based methods do not distinguish between live and dead bacteria, and there has been considerable interest in the use of fluorogenic indicators of metabolic activity or membrane permeability of single cells.[42,44,128,184] When used in combination with labeled antibodies, these stains can give an indication of the viability of specific organisms in a mixed flora.

However, metabolic activity and membrane permeability can be transiently affected by cell injury, and this will affect the response of cells to the different probes. The apparent absence of metabolic activity could mean either that a cell is dead or that it is injured or otherwise metabolically quiescent, and resuscitation is required to distinguish between the two states. The ability to reduce tetrazolium salts was temporarily lost when cells of *Listeria monocytogenes*

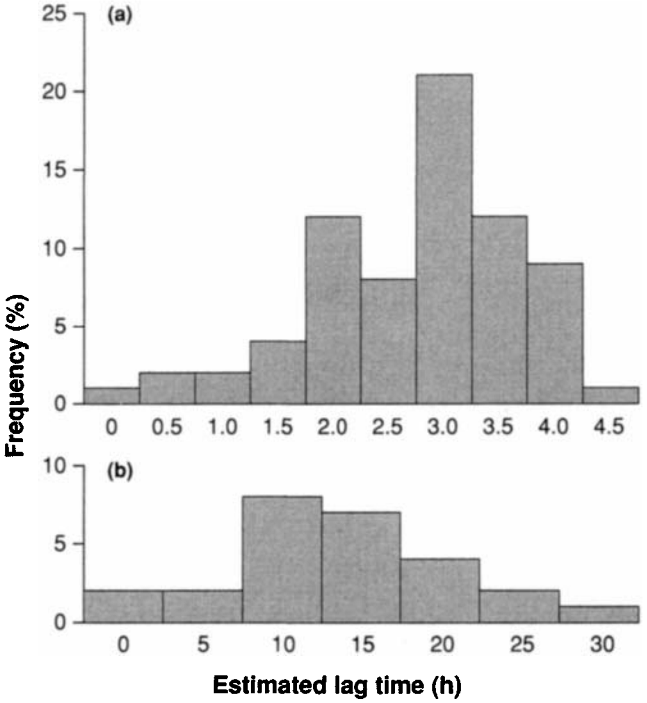

Figure 15-9 Distribution of Lag Times in *Salmonella typhimurium.* **A**, unheated cells; **B**, heat-injured cells. *Source:* Data from P.J. Stevens et al., The Use of an Automated Growth Analyzer to Measure Recovery Times of Single Heat-Injured Salmonella Cells, *Journal of Applied Bacteriology,* Vol. 83, pp. 445–455, © 1997, Blackwell Science Ltd.

were exposed to mild heat stress, but this capacity was restored during resuscitation in liquid medium.[27]

A recently described method for detection of *S. typhimurium, Pseudomonas aeruginosa,* or *C. jejuni* employs replication of a species-specific bacteriophage as an amplification strategy.[118] Selective media are unnecessary in this method but whether sublethal injury would affect the ability to adsorb or propagate phage is not yet clear. Messenger RNA has a half-life of only a few minutes in bacterial cells and its presence has been suggested as an indicator of viability.[14,91,166] It is likely that the presence of some mRNA types would temporarily disappear as a result of injury, in which case resuscitation would be necessary before probing.

15.8 THE ROLE OF SUBLETHAL INJURY IN COMBINED TREATMENTS FOR PRESERVING FOOD

The maintenance of homeostasis requires an intact semipermeable cell membrane and the expenditure of energy. Therefore, any treatments that disrupt membranes or interfere with energy conservation will hinder or abolish the homeostatic capacity and will eventually lead to degeneration and death. If membrane structure or function is disrupted, even relatively mild environmental stress can prevent growth or kill the cell. Fruitful strategies for combined treatments based on sublethal injury might therefore aim to (1) damage membranes, (2) impose an external stress, and (3) arrange conditions such that repair of injury is delayed or prevented.

Most physical stresses such as heating, freezing, high-pressure treatment, dehydration, and high-intensity electric fields cause damage to both outer and cytoplasmic membranes of Gram-negative bacteria and also to the Gram-positive wall and membrane. Examples of combined treatments that probably involve membrane damage are heating at low pH; high pressure and heat; and heating with ultrasound energy and a slightly raised hydrostatic pressure.[46,61,62] Physical stresses, such as exposure to high pressure or treatment with chelating agents, damage the Gram-negative outer membrane and sensitize cells to nisin and lysozyme, thus offering possibilities for use in combination treatments.[67,84] If repair processes are slowed, for example, by holding at low temperature, or additional metabolic burdens imposed, cell death ensues albeit slowly.

In calculating safe food processing treatments, it is normal to specify a certain number of log reductions that must be achieved, eg, 6 to 7 for organisms like *Salmonella.* The use of combination treatments effectively increases the death rate either by enhancing lethality during the treatment itself, or by ensuring that any injured survivors subsequently die on continued exposure to inimical external conditions (Figure 15-10). Because there is a spectrum of degrees of injury in surviving populations, the probability of growth under restrictive conditions will depend on the particular distribution of injury within surviving populations. There appears to be no theoretical treatment of this.

The limiting factor in applying mild combination treatments is often the presence of bacterial spores, particularly of psychrotrophic clostridia. However, some combined treatments such as ultraviolet light combined with hydrogen peroxide, heat, and acid, and heating followed by ionizing radiation are effective even against spores.[187] There is some evidence that damaged spores may die if held at ambient temperatures under some conditions that do not permit growth; this requires further investigation.[98] The application of combination treatments in food preser-

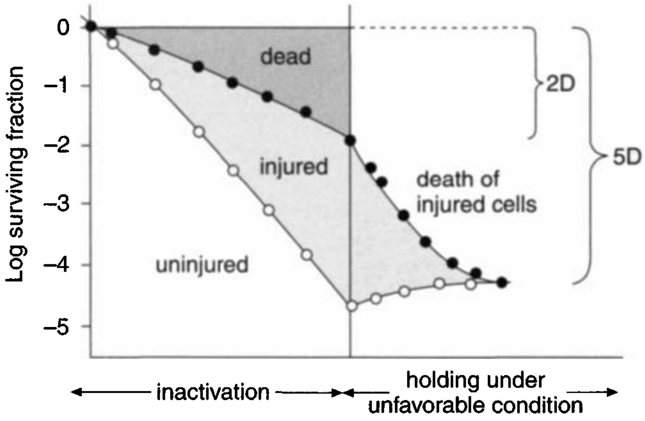

Figure 15-10 Effect of Preventing Repair of Sublethal Injury on Inactivation of Microbes. If repair of injury is prevented by unfavourable post-treatment conditions, the effective extent of inactivation is increased from 2 to 5 log units reduction in this example.

vation is not new, and many traditional foods such as salami-type fermented sausages and pasteurized cured meats rely on combination treatments for their safety and stability. However, many new combinations are being tested and our understanding of the physiological mechanisms involved is still rudimentary. A better knowledge of the role of sublethal injury in combined treatments would help in the development of new preservation methods that provide improved quality while maintaining product safety.

15.9 CONCLUDING REMARKS

The phenomenon of sublethal injury in bacteria has been recognized for over 50 years, and it is now possible to explain, in general terms at least, many of the altered phenotypic properties of such cells in terms of injury to particular cell structures, as discussed in this review, although detailed physiological explanations are often lacking. The VBNC state has been recognized more recently and continues to excite controversy. The following questions often arise. "Do VBNC cells really exist?" "Are they more resistant than normal cells?" "What should the food microbiologist be doing about them?"

If one accepts that bacterial viability implies the capacity to multiply under suitable conditions, then the mere detection of metabolic activity in intact cells (eg, the capacity to reduce INT or elongate in response to nutrients) is not sufficient grounds for assuming they are alive. In a few cases (eg, starved *M. luteus*) the viability of cells that are temporarily nonculturable (or fastidious to use the terminology suggested here) has been demonstrated by applying a resuscitation treatment that restores full culturability. However, for most organisms described as VBNC, unequivocal resuscitation data are lacking and quantitative estimates of numbers of VBNC in populations of cells are almost nonexistent. This does not mean that VBNC cells of the common pathogens do not exist in food, it simply means that the case has not been rigorously proven and that it is not yet possible to gauge the extent or significance of the phenomenon. Given the long periods over which membrane integrity and metabolic activity can persist in nonculturable cells, it would be particularly helpful to have comparative information on the longevity of such functions in unequivocally dead cells, eg, those killed by radiation.

The distinction between injured and "nonculturable" states was originally based on perceived differences in the causes of these conditions and in the associated physiological characteristics. Sublethal injury was usually associated with exposure to physical or chemical stress and was characterized by the loss of ability to grow on selective, but not on nonselective media. VBNC cells are more typically associated with starvation states, and fail to grow even on nonselective media. These distinctions have become blurred because the term VBNC is now also applied to cells produced by sudden physical insult, such as aerosolization, that need betain for recovery (whereas salmonellae in milk powder that need slow rehydration to recover are called injured). Differences based on physiological properties are also less clear with the recognition that injured cells also may fail to grow on rich nonselective media, eg, because they are sensitive to oxidative stress.

The risk posed by different pathogens in foods, and therefore the stringency of sampling schemes and detection methods, depends on numerous factors including the infective dose, the severity of illness caused, whether subsequent food handling will increase or decrease the risk, the likelihood of spread within the community, and exposure of susceptible groups. Clearly the presence of highly infective pathogens, even injured ones, in foods that are to be consumed without further treatment is considered unacceptable, particularly where susceptible groups in the population are at risk or if there is a chance of further microbial growth in the food. In such cases, it is very important to detect even severely injured cells. Current resuscitation methods may not allow full recovery of injured cells that require strictly anaerobic conditions for repair or those needing very long repair times. To rectify these possible deficiencies would present substantial practical difficulties for routine laboratories. Therefore, the importance of anaerobiosis in recovering injured bacteria and the significance of severely injured cells need clarifying.

A better understanding of the distribution of properties in populations of stressed cells would allow the effect of cell injury to be included in risk assessment exercises, and would provide a basis for estimating the lethality of combined processes that depend on inhibiting sublethally injured cells. Experimental and theoretical approaches to studying the distribution of lag and repair time within bacterial populations have already begun,[10,173] but corresponding stochastic approaches to other relevant properties of injured cells, such as resistance to acid, heat, and food preservatives, or virulence, have not been attempted. With the advent of flow cytometry and cell sorting, the methods for approaching the problem of individual cell variation are now available.

Understanding the basis of the fastidious phenotype (ie, extreme sensitivity to recovery conditions) is a central question for microbial physiologists and geneticists interested in microbial survival. Only when we know the underlying mechanisms will we be able to decide whether VBNC cells represent a class that is distinct from injured cells and whether they are more resistant or require a different approach to recover them.

16 Principles and Application of Predictive Modeling of the Effects of Preservative Factors on Microorganisms

József Baranyi and Terry A. Roberts

CHAPTER CONTENTS

16.1 Introduction
16.2 Overview
16.3 Modeling microbial responses
  16.3.1 General considerations
  16.3.2 Modeling thermal death
  16.3.3 Modeling growth
  16.3.4 Modeling nonthermal inactivation
16.4 Computational aspects of creating predictive models: a new modeling approach
  16.4.1 Is a new modeling approach needed?
  16.4.2 Exponential growth
  16.4.3 Transition from exponential to stationary phase
  16.4.4 Transition from lag to exponential phase
  16.4.5 Model implementation
  16.4.6 Accuracy of predictive models
16.5 Prospects
References

16.1 INTRODUCTION

In the first part of this chapter, the history and progress of an area of food microbiology known as *predictive microbiology* are summarized along with guidelines for the efficient acquisition of data for effective modeling. In the second part, mathematical aspects of modeling are addressed. Finally, topics that require further research effort if modeling is to be used more widely as a support tool in food microbiology are identified.

The safety and shelf life of food products have traditionally been estimated by challenge tests, or inoculated pack experiments, the food being inoculated with the microbe(s) of concern, and stored under representative, and often abuse, conditions. After storage, the food is tested microbiologically to determine whether the inoculated microbes have multiplied, survived, or lost viability. Retrospectively, some account is taken of properties of the food such as pH and percent salt-on-water or water activity (a_w), and the temperature of storage. Much reliance has been placed on such relatively crude tests, although the circumstances of the challenge test often differ substantially from the range of conditions that may be experienced during food processing and storage. Care must be taken to ensure that introducing the microbial challenge into the food does not change the local environment, eg, by introducing water with the inoculum, thereby facilitating local microbial growth that would not have occurred if water had not been added. It is common practice to use a relatively large inoculum in challenge tests using pathogenic bacteria, commonly 10^3–10^6, justified as giving the results "a margin of safety." However, assurance that such a large inoculum mimics the behavior of a smaller number of pathogens is weak. Such high numbers are not representative of the numbers of pathogens normally present in raw and processed foods, and there is evidence that growth can occur more readily from high numbers than from low numbers.[65] "Predictive microbiology" aims to overcome many of the disadvantages of challenge testing, particularly to allow the effects of combinations of factors on microbial growth and survival to be mathematically modeled.

16.2 OVERVIEW

The history of predictive microbiology was reviewed in admirable detail by Ross and McMeekin[71] who traced its origins to a number of initiatives. These initiatives included the following: research on fish spoilage in the United Kingdom (UK)[76] and Australia[55]; recognition that even so-called "rapid" microbiological methods were still relatively slow to provide the essential information whether microbes grew or died[64]; attempts in the United States (US) to define combinations of factors that would prevent pathogen growth and toxin formation[31]; and work in Canada to draw together the results of many apparently disparate experiments on *Clostridium botulinum*.[36] The ready availability of powerful personal computers and user-friendly software that encouraged microbiologists to explore areas of statistics and mathematics also contributed. Those uncoordinated interests, together with attempts to define the boundaries of "growth–no growth" of pathogens[62,63] led to results of complex experiments being expressed as equations that predict the probability of growth and toxin production in *C. botulinum*.[14,26,68]

The development of predictive microbiology received a huge boost after the UK Ministry of Agriculture Fisheries and Food reviewed possible topics for new research programs and decided, in 1988, to fund a coordinated program on bacterial pathogens to:

1. obtain systematic data on microbial growth and death for different temperatures, pH values, water activities, and preservatives
2. treat the data mathematically to make models of the microbes' behavior
3. ensure that the models mimic the microbes' behavior in a range of growth and death conditions
4. "validate" the model by comparison with independently published scientific data or by selected challenge tests.

At the time such targets were ambitious. There was no doubt that data could be generated, but experience of modeling such data was limited. There was much argument about whether models produced from laboratory experiments in media would be relevant to microbial growth in foods, or whether models should be produced from growth data in the foods in question. The background microbial flora was also believed to play some role in determining the rate and extent of growth of pathogenic bacteria.

In 1992, the outputs of that research program led to a "bureau service" based on the database and models derived from it. However, it was a somewhat cumbersome procedure and did not prove popular with the food industry. The bureau service was replaced in 1994 by the commercially available software Food MicroModel, running under Windows™. Work was also initiated in the US where the US Department of Agriculture undertook a similar program, modeling the growth and death responses of bacterial pathogens, leading to the software Pathogen Modelling Programme,[15] initially available running under DOS, and the most recent version under Windows™.

Interest in predictive microbiology in other European countries was fostered under a Food Linked Agricultural and Industrial Research (FLAIR) Concerted Action program on "Predictive Modeling of Microbial Growth and Survival in Foods" (CA No. 5, COST 905), and a FLAIR Shared Cost program on "Computer-Aided Process Design Procedures to Improve Quality and Safety of Products with a Limited Shelf-Life" (AGRF-DT91-0047), each from 1989 to 1993. The network of scientists in those programs has been maintained and expanded through COST 914 "Predictive Modeling of Microbial Growth in Foods" (1994–99), within which four subgroups have been established to explore topics identified as important to the improvement and further progress of predictive microbiology viz.:

1. validation of predictive microbiology in a wide range of European foods
2. instrumental methods for data capture for advanced predictive microbiology
3. exploration of mixed population effects in predictive microbiology
4. modeling microbial survival to eliminate pathogens from foods.

16.3 MODELING MICROBIAL RESPONSES

16.3.1 General Considerations

Challenge tests have long been recognized as expensive, slow, and demanding on facilities and microbiological skills, and as providing only modest assurance that the microbial behavior in the challenge test would be repeated in the food product during distribution and sale. Knowledge acquired in challenge tests is not cumulative, and when a product formulation, packaging, or distribution system changes, challenge tests must be repeated. The literature is witness to each new bacterial hazard being investigated in a variety of foods and a range of environmental conditions. Despite the vast amount of information on the growth and death responses of bacterial pathogens, no serious attempt had been made to bring that information together in a concise and readily usable form, until that by the International Commission on Microbiological Specifications for Foods (ICMSF).[38]

An alternative to challenge tests would be to understand sufficiently the responses of the microbes of concern to the main controlling factors in the food environment, to build a cumulative store of knowledge, and to develop the means of interpolating calculated microbial responses. Microbiologists have long dreamed of being able to model the growth and death of microbes in foods. The prospect of not having to repeat challenge tests when the responses are confidently assured was embodied in the term "predictive microbiology." Before any data were generated within the major programs of research mentioned above, numerous points of debate arose over the experimental approaches, choice of media, choice of organism, etc. Protocols had not been scrutinized widely and agreed, so any advice and comments were based on individuals' particular experience. No assumptions could be made that growth in laboratory media would necessarily mimic confidently growth in foods. Neither was it clear how many factors would need to be considered to enable accurate predictions to be made, so the early experiments tried to identify how much of the microbial response could be explained by the effects of a small number of controlling factors. As work progressed, a number of important principles and guidelines emerged that together led to effective protocols for predictive modeling, as summarized below.

Culture medium: In general, foods are rich in nutrients, so laboratory media chosen for modeling should be rich also, rather than minimal or likely to lead to early nutrient depletion during the growth of cultures. It is unwise to rely on a single medium for all organisms, rather a rich medium should be selected that is designed for the organism and likely to allow growth approaching the maximum possible growth rate.

Choice of organisms: Debate continues whether models should be developed using a single strain of a pathogen or spoilage organism or using several strains mixed in a "cocktail." Using a single strain gives a more precise definition of its responses, but strains of the same species may vary in their response, especially in suboptimal conditions. If a single strain is used, it should have been screened against the conditions to be modeled and have been shown to be representative of other strains of that organism, ie, similarly tolerant of low water activity and low pH, etc, and with similar temperature characteristics. Ideally, recent isolates, for example, from spoilage situations, should be used. Strains held for long periods, for example, in culture collections, may have lost important resistances or other characteristics. Many modelers have relied upon "cocktails" of strains to obtain a response, which takes account of the fact that one strain may grow at a slightly lower temperature, while a different strain may be slightly more tolerant of low pH. By using "cocktails," it is hoped that the model includes all the variations and, most importantly, any extremes of response.

Pathogens: Strains that have been associated with recent outbreaks of illness should be used wherever possible. As with spoilage organisms, strains that have resided in culture collections for long periods should be avoided to avoid losing any important property through repeated subculture. It should be recognized that minor differences in responses may occur within species, eg, in different serotypes of the same organism. However, modeling every important serotype separately is usually an impossible task and the only realistic solution is to include in the "cocktail" representatives of all the important serotypes.

Maintenance of organisms: It is possible that repeated subculture, even during the course of a data generation program, could result in changes similar to those found in old cultures. Data generation usually occurs over a relatively few months and nonessential subculturing should be avoided. However, even when additional data on pathogens have been derived some months later, after the completion of an initial series of experiments, those new data have been found generally to replicate earlier data adequately so that this has not proved to be a serious problem.

Preparation of the inoculum: During the early evolution of growth modeling studies, inocula were prepared in a standard manner, usually growing under near-optimal conditions to reach the exponential phase. Subcultures were then made and placed into a range of growth conditions, some near optimal, others judged to be close to conditions that would not support growth. If the inoculum was prepared by subculturing from conditions identical to the intended growth conditions, a different growth response may result, eg, in experiments to investigate growth at low temperature. In particular, the lag phase is generally most affected. However, the differences between the two responses have not been extensively quantified and most modelers regard the additional complexity of the latter procedure a disincentive. One important consequence, therefore, is that growth rate is usually modeled much better than lag time (see below). While this effect of "preconditioning" prior to subculture is well recognized in growth modeling, it has not been identified in survival modeling, ie, under conditions where growth cannot occur, but where it may also be important.

Changing conditions during growth: A conscious decision is usually taken to model growth, survival, and death as functions of the initial conditions of pH, water activity, preservative concentration, etc., at constant temperature in order to keep experimentation as simple as possible. In more sophisticated modeling, it becomes necessary either to generate models under changing conditions, or to show that models developed under a series of static conditions can be satisfactorily predictive when applied to those that change.

Aeration: When deciding on experimental approaches to the generation of data intended for modeling, aeration of cultures of aerobic bacteria should be considered. Shaking, combined with the use of a small volume relative to the size of the container, appears a simple solution, but rarely achieves good oxygen transfer into a culture as the concentration of organisms, and therefore their oxygen demand, rises. Gassing makes experimentation more complicated and may be justified where the effects of oxygen on growth are known to be substantial. However, it has generally been found that predictions from many existing models that were derived using static cultures appear to mimic adequately the documented responses of bacteria in and on stored foods.

Sampling: Two different approaches have commonly been used: (1) a single culture vessel is sampled repeatedly during storage, or (2) replicate cultures are derived from a single inoculated culture vessel, one being destroyed by sampling at each time interval. Which is used is a matter of personal choice. The former offers a more evenly mixed culture, but suffers from a greater risk of possible contamination, especially if the incubation period is protracted. The latter is effective and flexible as long as a sufficient number of replicates is provided to take account of unexpected slow growth. Either approach must provide a sufficient number of estimates of viable numbers to permit the inflexions in growth curves to be characterized, ideally of the order 12 to 20 estimates per curve.

16.3.2 Modeling Thermal Death

Although some workers regard modeling of microbial responses to food-related environments as novel, food technologists have for many years applied models of microbial death in major food processes worldwide, eg, to ensure sufficient inactivation of spores of *C. botulinum* in low-acid canned foods via the 12-D concept, the minimum heat process to inactivate 10^{12} spores, based on heat resistance studies on spores of *C. botulinum*.[28] This approach, as with all current microbial growth and death modeling, is empirical, interpreting the response of the organism without understanding the underlying mechanisms, in this case, the mechanism of spore death. Similarly, minimum processing times for elimination of *Salmonella* at a range of minimum internal temperatures[35] led to Guidelines and Good Manufacturing Practices[1] addressing the problems of cooking fresh and cured beef with respect to survival of *Salmonella*, and similar approaches have been made with respect to *Listeria monocytogenes*, *Escherichia coli* O157:H7, and others, all based on empirical models of thermal inactivation.

16.3.3 Modeling Growth

Modeling microbial growth has a long history in the fermentation industry, where the objective has been to maximize the generation of biomass by optimizing the effects of growth temperature and the supply of substrate(s). Likewise, in the production of fermented products of milk, meat, fish, and vegetables, rapid growth of the lactic flora and efficient fermentation are essential first steps to providing a wide range of traditional, safe products. In most other circumstances, however, the goal of the food microbiologist is to prevent, or minimize, microbial growth, rather than to optimize it.

Simple growth models have helped the identification of critical limits for microbial growth and aided the development of processing guidelines that give greater assurance of safety, eg, the Food Safety and Inspection Service (FSIS) directive[83] on time/temperature guidelines for cooling heated products is designed primarily to minimize growth of *Clostridium perfringens*. The identified control points, minimum and maximum holding temperatures, and cooling times were based on data derived from a comprehensive study of the growth of *C. perfringens* in chili.[10]

The number of factors that affect the growth or survival of foodborne microbes is large, including temperature, pH and the nature of the acidulant, water activity and the nature of the humectant, oxygen availability, redox potential, preservatives, etc. All of these factors need to be kept in mind when assessing whether a microorganism could pose a problem in a particular food system. The expectation of complex relationships between a large number of controlling factors, demanding huge experiments, had a negative effect on the progress of microbial growth modeling. Investigating all the identified factors at even a few levels would be beyond the resources of most researchers.

Studies of the combined effects of several controlling factors in food systems began more than 25 years ago. In the 1970s, research characterizing the effectiveness of sodium nitrite against *C. botulinum* in model systems and cured meats expanded because of interest in minimizing formation of nitrosamines without loss of antibotulinal activity or shelf life.[2,16,27,63,66] However, little of that research was used to construct models, perhaps due to insufficient systematic data, or lack of availability of, or access to, effective modeling techniques and because computers were not widely available. Nevertheless, that early work clarified the relative importance of the main controlling factors, and identified the need for a modeling approach. An early application of response surface analysis techniques to food microbiology[75] demonstrated that of 16 ingredients in a soy-based ground meat analog, only 4 had a significant impact on the growth of *C. perfringens.*

Probability Models

Hauschild[36] estimated the probability that a single spore of *C. botulinum* would germinate and produce toxin in a food, drawing together results from different authors. Other investigators systematically estimated the effects and interactions of a range of factors on the probability of germination and outgrowth of *C. botulinum.*[3,50] Other probability models have been published for toxin production by proteolytic strains of *C. botulinum* types A and B[36,43,68,87] and growth of *Zygosaccharomyces bailii.*[19]

Although such models indicated only the probability of growth or toxin production under defined conditions of temperature and time, the most significant factors and interactions influencing growth were clearly identified. The probability of growth quickly gives an indication of the safety implications of changes in product formulation or in storage conditions. Conclusions were sometimes unexpected, for example, growth of *C. botulinum* was shown to be unlikely to occur in bacon, which was receiving considerable attention and research, whereas products that had largely been ignored, such as turkey rolls, were less safe.[36]

Kinetic Models

Approaches to estimating the growth kinetics, particularly the lag phase and the maximum growth rate, vary in their mathematical complexity, but have similar aims, eg, the "square root,"[47,59] linear Arrhenius,[23] nonlinear Arrhenius[14] relationships, and the use of cardinal values from the literature.[72] Exploring the effects of several controlling factors at the same time has most commonly modeled derived growth parameters against the controlling factors by a response surface approach.[9,17,32,45]

More recently, dynamic mathematical models have been developed. The advantages and disadvantages of these and some of the potential pitfalls in their use have been discussed.[4,5,49] A simplification of the assumption that the state of a cell population can be defined by the physicochemical environment (temperature, atmosphere, substrate, etc) and the intracellular conditions[29] has been used in a new dynamic model.[4,5] The environment dependence of the maximum specific growth rate and the lag (or their reparameterized forms) have sometimes been modeled independently, although it has long been recognized in practice that there is often a high correlation between them. The new model addresses this problem by taking the product of those two parameters to be constant.[4]

It is important to be able to predict the course of bacterial growth under a time-temperature profile that changes with time. If the temperature remains within the range that allows growth, instantaneous adjustment of the specific growth rate to the temperature changes can be assumed if the cells are in the exponential phase.[11,30,51,52] The new model also makes it possible to predict the course of bacterial growth when the temperature changes in the lag phase during which the cells adjust to a new environment.

A serious hindrance to the furtherance of modeling as an approach has been a deeply rooted belief that the natural "spoilage" flora of a food influences the multiplication of any pathogen(s) present. However, when "predictions" from models developed in laboratory media are compared with measures of growth in foods, and account is taken of the pH, % brine (or a_w), and temperature, the estimates are often very similar. The conclusion that must be drawn is that much of the response of the pathogens can most often be explained by a relatively small number of controlling factors, and that in many instances, the growth response is affected little by the spoilage flora. Similarly, in most instances the composition of the food itself plays a minor role in determining the microbial response, contrary to earlier beliefs that the nature of a food would be a key determining factor.

Predicted growth responses from different models have been compared extensively.[45,78-80,85] The agreements between predictions of growth rate and observed values have, in general, been good. Nevertheless, in some instances the predicted growth responses derived from studies using laboratory media do differ from the observed, published or challenge test, values. The differences are sometimes clearly due to factors not included in the model such as nutritional factors, naturally occurring antimicrobials or added preservatives, for example, nitrite in the food or carbon dioxide in the atmosphere above it. Some foods contain natural antimicrobial systems, eg, eggs.[21] In other cases, the structure of the food plays a role, perhaps by limiting diffusion of substrate or oxygen to the microbe, or acid produced away from it.[12,67] There are examples where the response of a pathogen is influenced by the spoilage flora, in particular by the local change in pH caused by its growth. Several models with more than three factors have been developed to accommodate the additional controlling factors.[17,45]

If the observed response in a particular foodstuff still differs substantially from that predicted by a model containing all the known major controlling factors, it is important to determine the reasons, and to keep a record of them. Some of the problems that arise and need to be addressed are identified in a recent review.[48]

16.3.4 Modeling Nonthermal Inactivation

In foods, there are sometimes conditions of temperature, pH, and a_w under which multiplication of bacteria cannot occur but the conditions are not lethal. Vegetative pathogens may be able to withstand adverse conditions for long periods, often months, without losing their viability. Effort has already been put into modeling those responses.[39,86] Data on survival in adverse conditions are available for *Listeria monocytogenes*,[18,20] *Yersinia enterocolitica*,[42] and *Staphylococcus aureus*[89] but, like the growth models, these models are empirical and, as yet, without any basis in the physiological responses of the microbes during loss of viability or survival.

16.4 COMPUTATIONAL ASPECTS OF CREATING PREDICTIVE MODELS: A NEW MODELING APPROACH

16.4.1 Is a New Modeling Approach Needed?

Although currently used models of microbial growth and survival sometimes fail to predict microbial behavior in particular foods, the reasons for failure, as indicated above, are often known or suspected. Usually, the cause of the failure is not inadequacy of the model, but lack of knowledge of all the important factors in the food. It is therefore not likely that radically new models *per se* will lead to improved predictions, though new approaches, such as that proposed below, may be of some value. For example, although biotechnology has produced many models of microbial growth (see, for example, the excellent reviews of Roels and Kossen[69] or Nielsen and Villadsen[54]), most of those models cannot simply be copied and applied to the different purposes in food microbiology. The reasons for this are as follows: (1) with the exception of fermented foods, the goal of food microbiologists is to minimize or prevent microbial growth rather than optimize it, as is often the case in biotechnology; (2) the cell concentrations of interest in food microbiology, particularly with regard to pathogens, are much lower than in biotechnology, where typically concentrations much greater than 10^8 or so cells ml^{-1} are encountered. As a consequence, some models validated at high cell concentration, eg, turbidity, biomass, or conductance measurements, should not be applied directly without establishing the relationship between the indirect measurement and cell numbers at lower bacterial concentration; (3) in food microbiology, the lag phase and the factors that determine its duration are very important, while it is less so in biotechnology. On the other hand, well-established models of the transition from the exponential to the stationary phase, like Monod's model,[53] lose significance in food microbiology because substrate limitation is rarely important until microbial concentrations reach the very high levels associated with spoilage. Below, the basic elements that underpin most models of microbial growth are summarized. Then a new, and hopefully improved, approach will be developed.

16.4.2 Exponential Growth

The following basic model of population growth has been widely used in biological sciences since Malthus.[44] Suppose that, at the time $t = 0$, the bacterial concentration is x_0. Let $x(t)$ denote the concentration at the time t.

It is assumed that the controlling quantities are not affected by the bacterial growth and metabolism. Therefore, of course, we do not model them. If an $x(t)$ function describes the time variation of the concentration of a population then the instantaneous *specific* growth rate, $\mu(t)$, at the time t is defined by

$$\mu(t) = \frac{\frac{dx(t)}{dt}}{x(t)} \tag{1}$$

In other words, the specific growth rate is the rate of increase *per* the population density that has produced that increase. The pure exponential growth model assumes that the specific growth rate of the population is constant:

$$\frac{dx(t)}{dt} = \mu x(t) \tag{2}$$

Introduce the notation

$$y(t) = \text{Ln}\, x(t) \tag{3}$$

$$y_0 = y(0) = \text{Ln}\, x(0) = \text{Ln}\, x_0 \tag{4}$$

By means of this, the differential equation (1) can be written as

$$\frac{dy(t)}{dt} = \frac{d(\text{Ln}\, x(t))}{dt} = \frac{\frac{dx(t)}{dt}}{x(t)} = \mu \tag{5}$$

Therefore, while the instantaneous *growth rate* can be represented by the slope of the "$x(t)$ vs. t" curve at the time t, the *specific growth rate* can be measured by the slope of the "Ln $x(t)$ vs. t" curve (Figure 16-1A and B). In practice, however, it is more usual to plot the 10-based logarithm of the concentration, log $x(t)$ against time. In this case, the slope of the "log $x(t)$ vs. t" curve is Ln 10 = 2.3-times less than μ, the "real" specific growth rate.

The solution for the differential equation (1), at the given initial value, is the following:

$$x(t) = x_0 e^{\mu t} \tag{6}$$

or, expressed by the natural logarithm of the cell concentration as follows:

$$\text{Ln}\, x(t) = y(t) = y_0 + \mu t = \text{Ln}\, x_0 + \mu t \tag{7}$$

Again, the usual log $x(t)$ concentration can be obtained by using the conversion factor Ln 10 = 2.3, keeping in mind that this is the factor between the natural and the 10-based logarithm:

$$\log x(t) = \log x_0 + at \tag{8}$$

where $a = \mu/2.3$. This is in accord with what has been mentioned, that the slope of the growth curve on the $\log_{10}$ scale, a, differs from the specific growth rate by the factor 2.3.

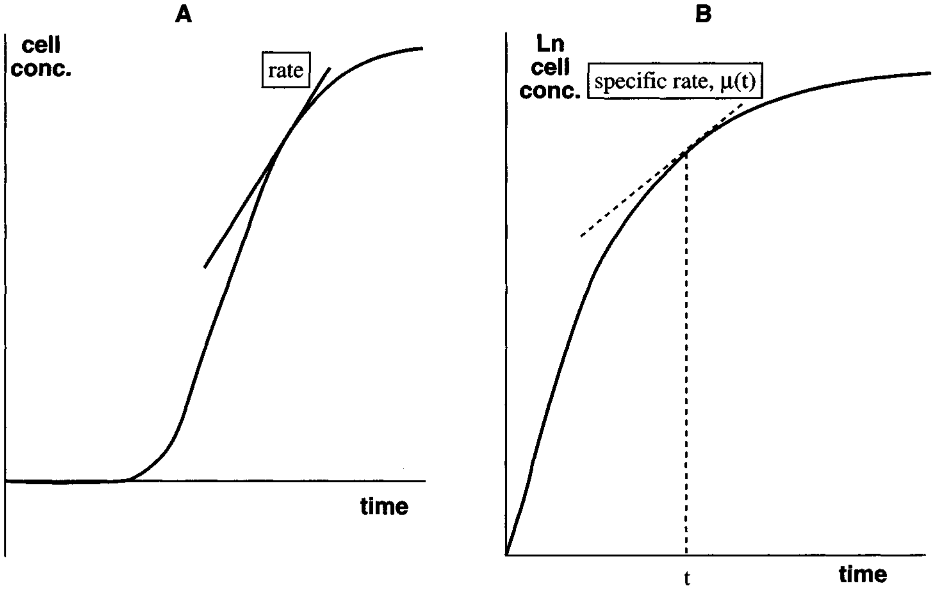
One can ask, what time interval is needed for the population to double? From the equation (6), simple calculation shows that if

$$t_D = \frac{\text{Ln}\, 2}{\mu} \approx \frac{0.69}{\mu} \tag{9}$$

then

$$x(t + t_D) = x_0 e^{\mu(t+t_D)} = e^{\mu t_D} x_0 e^{\mu t} = 2x(t) \tag{10}$$

The rate is measured on linear scale, while the specific rate on (natural) log scale.



If the cell concentration was modeled by a classical sigmoid function (in this case Gompertz) then, on the log scale, lag is not apparent.

Figure 16-1 The Difference between Growth Rate and Specific Growth Rate Using the Same Dataset.

Therefore, the doubling time is constant for exponential growth, and it can be calculated from the specific growth rate by means of formula (9). From a, the slope of the "log $x(t)$ vs. t" curve, the doubling time can be calculated as

$$t_D = \frac{\log_{10} 2}{a} \approx \frac{0.3}{a} \tag{11}$$

The doubling time, t_D for a population is not necessarily the same as the mean of the generation times of the individual cells, t_G.[73] They are equal only if the cells divide synchronously. If they do not grow synchronously, then the average cell cycle time of the individual cells is somewhat higher than the time necessary to double the whole population. For example, if the dynamics of the population can be closely related to the so-called Poissonian random birth process, which is widely observed in nature,[29] then the mean generation time of individual cells will be close to $t_G = 1/\mu$, which is almost 40% higher than $0.69/\mu$, the doubling time of the whole population.

16.4.3 Transition from Exponential to Stationary Phase

Let $x_{\max}$ be the maximum population concentration and let

$$y_{\max} = \text{Ln } x_{\max} \tag{12}$$

Suppose that the growth rate follows the model of Richards[61]:

$$\frac{dx(t)}{dt} = \mu_{\max} x(t)\left(1 - \left(\frac{x(t)}{x_{\max}}\right)^m\right) \tag{13}$$

Here, $\mu_{\max}$ is a model constant that can be called the (potential) maximum specific growth rate because the smaller the population concentration, ie, in the early exponential phase, the closer the specific growth rate is to $\mu_{\max}$. This is because, using the definition (3), we obtain the following:

$$\mu(x) = \frac{\frac{dx(t)}{dt}}{x(t)} = \mu_{\max}\left(1 - \left(\frac{x(t)}{x_{\max}}\right)^m\right) \tag{14}$$

However, as long as the actual cell concentration $x(t)$ is much smaller than its maximum, $x_{\max}$, the instantaneous specific growth rate is close to $\mu_{\max}$.

We express the solution of the differential equation (13) in terms of $y(t)$, the natural logarithm of the cell concentration:

$$y(t) = y_0 + \mu_{\max} t - \frac{1}{m}\text{Ln}\left(1 + \frac{e^{m\mu_{\max} t} - 1}{e^{m(y_{\max} - y_0)}}\right) \tag{15}$$

In the most frequently used form, the parameter m is taken to be 1, in which case the logistic function can be obtained for the bacterial concentration (not for its logarithm!). Indeed, expressing the above formula in terms of $x(t)$, at $m = 1$, one can obtain the following:

$$x(t) = \frac{x_{\max}}{1 + \left(\frac{x_{\max}}{x_0} - 1\right)e^{-\mu_{\max} t}} \tag{16}$$

This is the formula of the logistic function.

The model (14) states that the instantaneous specific growth rate of the population, $\mu(x)$, at the moment when the population concentration is x, is practically $\mu_{\max}$, until the population density becomes comparable to its maximum, $x_{\max}$. In other words

$$\frac{\frac{dx(t)}{dt}}{x(t)} = \mu(x) = \mu_{\max} u(x) \tag{17}$$

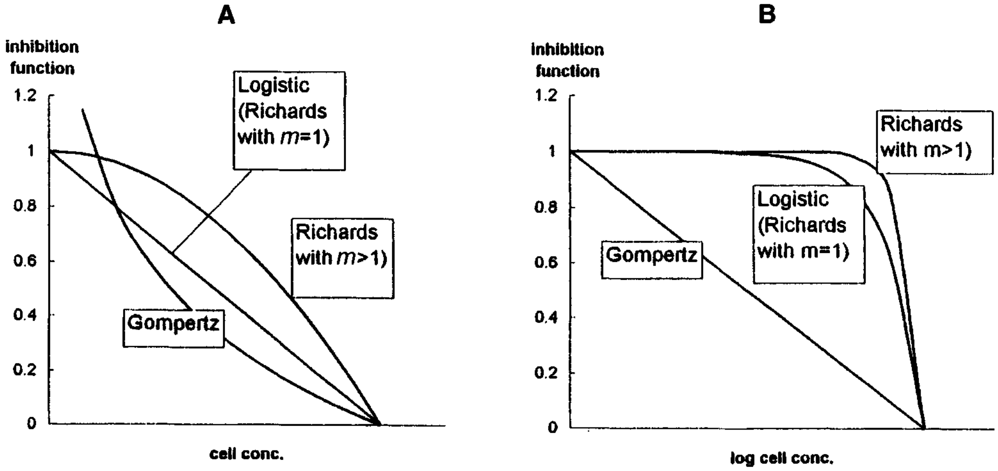
where $u(x)$ will be called an *inhibition* function. As the population concentration increases, the inhibition is stronger and stronger, ie, $u(x)$ is monotone decreasing and the population is less and less able to increase (Figure 16-2A and B). This structure is typical of all the models describing the transition to the stationary phase. The well-known models of Gompertz, Monod, etc, differ mainly in the way in which their inhibition function is derived.

Monod[53] modeled $u(x)$ with a Michaelis-Menten–type inhibition caused by the substrate concentration as shown here:

$$u(x) = \frac{S}{S + K_s}, \quad \frac{dx}{ds} = \frac{1}{-Y} \tag{18}$$

where K_s and Y are constant. As Baranyi and Roberts[5] pointed out, this model complies with the above definition of an inhibition function because it can be transformed into a model of the structure (17), with monotone decreasing inhibition function.

Another well-known model can be obtained by limiting the exponential growth as suggested by Gompertz.[34] Here, the limiting function is logarithmic:



The shape of the inhibition function depends on the scale of the axes.

Figure 16-2 Modeling the Transition from the Exponential into the Stationary Phase by the $u(x)$ Inhibition Function. **A**, The inhibition function against x, the cell concentration. **B**, The same inhibition function against $\log x$, the logarithm of the cell concentration.

$$\mu(x) = \frac{\frac{dx(t)}{dt}}{x(t)} = c\mathrm{Ln}\left(\frac{x_{\max}}{x(t)}\right) \qquad (19)$$

If smaller and smaller x cell concentrations are considered, then the specific growth rate, $\mu(x)$, converges to infinity. The model constant c is certainly not the (potential) maximum specific growth rate, which quantity does not even exist (Figure 16-2A). The main difference between the shapes of the Richards and Gompertz inhibition function is that the former has a value between 0 and 1, while the latter has no upper boundary. Therefore, the Gompertz model is not suitable, for example, to extrapolate the specific growth rate (or generation time) of the cells when the concentration was lower than x_0.

Further details on similar models can be found in Rubinow[73] and Turner et al.[82] It is important to see that Richards' family of functions (including the logistic), as well as the Gompertz function, is a sigmoid curve only for $x(t)$, the bacterial concentration, but not for its logarithm, $y(t)$ (see Figure 16-1A and B). The typical representation of a bacterial batch culture, however, is to plot the logarithm of the cell concentration against time and, in most cases, the result is a sigmoid curve. A possible empirical curve-fitting procedure is to fit sigmoid functions, augmented with an additive term, to these data. This approach, especially with the Gompertz function, was followed by many authors in recent years in predictive microbiology.[17,32,90] The Gompertz model has deep roots in population dynamics[37] but if the Gompertz function is "modified" to apply to the logarithm of the population size, then it should not be referred to as the *Gompertz model.* The terms function and model should be differentiated.[5] The phrase "Gompertz function fitted to the logarithm of the bacterial concentration" is correct, but the same phrase with "Gompertz model" is not. The differential-equation-form[84] is another form of the same, "modified," Gompertz model.

16.4.4 Transition from Lag to Exponential Phase

The classical growth models (Gompertz, logistic, etc) applied to the cell concentration do not show sigmoid characteristics on the log scale (Figure 16-1B). Therefore, they are not suitable for modeling the lag phase as traditionally defined, ie, the intercept of the tangent to the inflexion with the initial concentration. According to that (Figure 16-3), the end of the lag phase is the intercept of the lower asymptote and the tangent drawn to the inflection point of the bacterial curve plotted on the log scale.[56]

The problems with modeling the lag originate from this geometrical definition. Lag should be interpreted only if there is a distinct time when the environment changes suddenly (such as at inoculation), which can be considered the beginning of the lag. This means that the so-called autonomous structure of the equation (17) (namely, that the in-

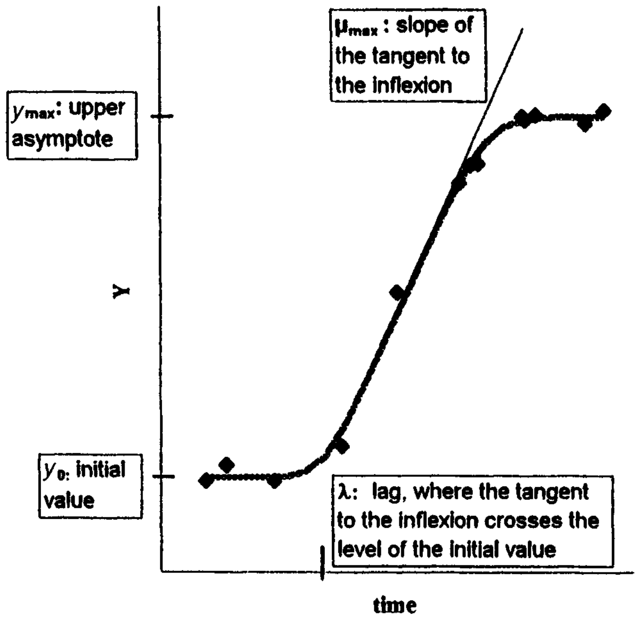


Figure 16-3 Bacterial Growth Curve Fitted by a Four-Parameter Sigmoid Curve.

stantaneous specific rate depends only on cell concentration) is not suitable to model lag phase.

For an individual cell, the lag is a waiting time spanning from the sudden change in the environment to the first division. At the population level, this waiting time has a distribution. The relationship between the distribution of the lag and the above geometrical definition is not at all straightforward.

Put the equation (17) in a different context. After rearranging

$$\frac{dx(t)}{x(t)} = \mu(x)dt$$

The left-hand side of this equation is an infinitesimal form of the probability that a randomly chosen cell divides in the $[t, t + \Delta t]$ interval. A probabilistic lag concept can be introduced as follows.

Multiply the right-hand side by the factor $\alpha(t)$, which expresses the probability that, at the time t, a randomly chosen cell is a daughter cell (ie, it is not from the initial generation). The proportion of these cells converges to 100% with time, therefore the values of $\alpha(t)$ is between 0 and 1 and monotone increasingly converges to 1 as t converges to infinity. The obtained relation reads as follows: *prob*(division happens in $[t, t + \Delta t]$) = $\alpha(t)\,\mu(x)\,\Delta t$.

Translating this model back to the population level:

$$\frac{\frac{dx(t)}{dt}}{x(t)} = \alpha(t)\mu(x)u(x) \qquad (20)$$

The probability distribution function $\alpha(t)$ is equivalent to the concept of *adjustment function* as defined by Baranyi and Roberts.[4] The $\alpha(0)$ initial value measures the proportion of the cells that are ready for the new environment.

The value $\alpha(t)$ determines not only the value of lag (λ, in what follows) but also affects the curvature from the lag to the exponential phase. For example, if

$$\alpha(t) = \begin{cases} 0 \text{ for } t < \lambda \\ 1 \text{ for } t > \lambda \end{cases}$$

then the curvature is a breakpoint, ie, the model of intercepting straight lines can be obtained.

Because there are no reliable measurements on the nature of this $\alpha(t)$ distribution function, some idealistic and empirical simplifications have to be introduced. Baranyi and Roberts[4] introduced a two-parameter adjustment function (which, as has been pointed out, is the same as the $\alpha(t)$ distribution function for the lag) based on the hypothesis that there is a rate-limiting intracellular bottleneck substance, $P(t)$, which must be built up during the lag. That substance is assumed to inhibit the growth according to a Michaelis-Menten kinetics, as follows:

$$\frac{\frac{dx(t)}{dt}}{x(t)} = \frac{P(t)}{K_P + P(t)}\mu_{\max}u(x) \qquad (21)$$

If, during the lag, that critical substance is exponentially growing, at a constant v specific rate, then the growth of the cell population can be described by

$$\frac{\frac{dx(t)}{dt}}{x(t)} = \frac{q_0 e^{vt}}{1 + q_0 e^{vt}}\mu_{\max}u(x) \qquad (22)$$

where $q_0 = P_0/K_P$. Therefore, the wanted distribution function can be written as

$$\alpha(t) = \frac{q_0}{q_0 + e^{-vt}} \qquad (23)$$

In this model, q_0, the ratio between P_0 (the initial value of the critical substance) and K_P (the Michaelis-

Menten constant) summarizes the "readiness" of the cells for the new environment. The parameter $\alpha(0) = \alpha_0 = q_0/(1 + q_0)$ is another measure of this readiness.

As can be proved mathematically, the mentioned geometrical measure of the length of the lag phase can be estimated by $\lambda = \exp(-\alpha_0)/v$.

Referring to the original paper for technical details, the adjustment model of Baranyi and Roberts[4] combined with Richards' growth model (see above) gives a differential equation, which can be solved explicitly:

$$y(t) = y_0 + \mu_{\max}A(t) - \frac{1}{m}\mathrm{Ln}\left(1 + \frac{e^{m\mu_{\max}A(t)} - 1}{e^{m(y_{\max} - y_0)}}\right) \quad (24)$$

where $A(t)$, the integral of $\alpha(t)$, can be considered as a gradually delayed measure of time:

$$A(t) = t - \lambda + \frac{\mathrm{Ln}\left(1 - e^{-vt} + e^{-v(t-\lambda)}\right)}{v} \quad (25)$$

16.4.5 Model Implementation

It is not easy, if at all possible, to fit the differential equation (22) to actual data using ordinary regression packages. This is why it is important to know whether the solution of a differential equation is expressible by a composition of elementary functions. If it is, then the solution is called explicit and it can be readily used in ordinary software packages, such as spreadsheets, for prediction. Such an expressible solution, however, is never guaranteed and, in fact, more often than not a randomly chosen differential equation will not have an explicit solution. In our case, it does exist, as described by the equations (24) and (25).

Another important difference between the model (22) and its explicit expression (24) and (25) is their applicability for time-dependent conditions. Baranyi et al.[6] demonstrated that the model (22) is also valid under (not severely) changing environmental conditions. Simply, the environment dependence of the maximum specific rate must be incorporated in the model: $\mu_{\max} = \mu_{\max}(E(t))$, where $E(t)$ is the environmental profile. However, the explicit solution (24) will not be valid anymore and, commonly, the model can be simulated only approximately on a computer. The need for predictions in dynamically changing environments makes it inevitable that growth models should be derived in their differential equation form rather than in an explicit form.

When using an explicit model for numerical purposes, like simulation or curve fitting, it is sometimes advisable to reparameterize the original model. It is possible that a different parameterization of a model is more advantageous for computation than the parameterization used to develop the model.[58] For a simple example, consider the expression exp(1000) • exp(–1000). When typing this into the computer, the result should be obviously 1. However, most packages would give overflow error when carrying out this statement. But if we rearrange the formula and type exp(1000–1000), there is no problem with the exact answer.

Similar rearrangement is necessary when using the formulae (24) and (25) for fitting, otherwise the numerical instability can result in error messages. Baranyi and Roberts[4] reduced the number of the parameters, specifically for bacterial counts, in the following way. They assumed that the accumulation of the bottleneck substance, $P(t)$, during the lag, happens at the same specific rate that will be later the maximum specific rate of the population ($v = \mu_{\max}$) and, introducing $n = v/\mu_{\max}$, they fixed the value of n as $n = 1$ and the value of m as $m = 1$ (logistic limitation at the transition to the stationary phase).

In order to fit data other than bacterial counts that show sigmoidal behavior, it is useful to reparameterize the equations (24) and (25) in such a way that the optimal curvature parameters do not depend on the scale of the data. For this reason, introduce the parameter $h_0 = v$ and, in return, drop the parameter v from the model. The value h_0 will be a dimensionless curvature parameter characterizing the transition from the lag to the exponential phase. The significance of this reparameterization is that the h_0 does not depend on the time scale used, and the shape of the transition from the lower asymptote to the linear phase remains the same after using, say, hours instead of days.

For the same reasons, it is worth reparameterizing the other curvature parameter, m, and using $M = m(y_{\max} - y_0)$ instead. The value M will describe the transition from the exponential to the stationary phase. The higher its value, the closer is the transition to a real "breakpoint" and the curvature does not depend on the used scale for the y axis (except, of course, for nonlinear transformations of that axis).

By fixing the h_0 and M curvature parameters, four parameters remain to be fitted: y_0, $y_{\max}$, $\mu_{\max}$, and λ. Fitting this model is comparable to the fitting of the classical growth functions like logistic or Gompertz, augmented by an additive term.[90]

Note that the parameter $\mu_{\max}$ is not exactly the steepest slope of the actual growth curve, but expresses a "potential" maximum specific growth rate that is characteristic to the population only if the initial concentration level is not very high. The difference between the steepest slope and μ_{max} is noticeable if the h_0 and M curvature parameters are small and/or y_0 is close to y_{max}.

The reparameterized form of the equations (24) and (25), with dimensionless h_0 and M curvature parameters, can be written as follows:

$$y(t) = y_0 + \mu_{max} A(t) - \frac{y_{max} - y_0}{M} \bullet \mathrm{Ln}\left(1 - e^{-M} + e^{-M} \frac{y_{max} - y_0 - \mu_{max} A(t)}{y_{max} - y_0}\right) \quad (26)$$

where

$$A(t) = t - \lambda\left(1 - \frac{1}{h_0}\mathrm{Ln}\left(1 - e^{-h_0 \frac{t}{\lambda}} + e^{-h_0\left(\frac{t}{\lambda} - 1\right)}\right)\right) \quad (27)$$

The equations (26) and (27) describe a (generally sigmoid) function with six parameters, two of which, h_0 and M, are curvature parameters that are not easy to fit and it is advised to keep them as fixed numbers. In our experience, $h_0 = 10$, $M=10$ are good empirical constants for them, for not very sharp curvatures.

Below, that BASIC subroutine is listed, which is used in an in-house program in the Institute of Food Research, UK, to fit sigmoid curves. The routine can be used, for example, in combination with the Levenberg-Marquardt method of the Numerical Recipes.[57,77] The routine returns with the function value y for the following input parameters:

`t:`	time
`mu, lag, y0, ymax:`	parameters μ, λ, y_0, y_{max} to be optimized
`M, h0:`	fixed curvature parameters
`M = 0:`	a symbolic value for y_{max} = infinitely large (upper asymptote does not exist)
`h0= 0:`	a symbolic value for the case when there is no lag

The routine also calculates the derivatives

$$\frac{dy}{d\mu}, \frac{dy}{d\lambda}, \frac{dy}{dy_0}, \frac{dy}{dy_{max}}$$

and stores them in the fields `dyda(1)...dyda(4)`.

Remember that `Log` is meant in BASIC as natural logarithm.

16.4.6 Accuracy of Predictive Models

As has been mentioned, the basic requirement is to predict the bacterial concentration, $x(t)$ for any time $t > 0$. For this, the variation of the main growth parameters with environmental factors such as temperature, water activity, etc, is modeled. The type of models used is extensively discussed in McMeekin et al.[49] Here we consider a practical concern: the accuracy of those models.

It is assumed that the potential maximum specific growth rate of the population achieved in a constant environment, as explained in the previous points, is an intrinsic growth parameter (independent of the experimenter and of the history of the cells). Of course, due to the inevitable biological complexity, replicate experiments show a certain variance. Under favorable conditions, the estimated standard deviation of the maximum specific growth rate of replicated *Listeria monocytogenes* growth curves using viable counts generated in the laboratory was about 7% to 10% of the average estimated value.[5] In accord with what follows, we say that the method of measuring the specific growth rate by the above way has about 10% error. Another possible terminology is to say that the method has an accuracy factor of about $p = 1.1$. This latter terminology was used by Ross[70] who defined the "accuracy factor" of a model as the antilog value of the average difference between the log(observed) and log(predicted) values of the modeled responses (generally specific rates or doubling times). The only modification we suggest to this definition is that the interpretation of the "average difference" should be not arithmetical average but square-root-average, consistently with the least squares principle of statistics. Therefore, let the "amended accuracy factor," p, be defined as

$$\log p = \sqrt{\frac{\sum\left(\log(observed) - \log(predicted)\right)^2}{n}}$$

where n is the number of observations and the summation is meant through these observations.

The advantage of this definition is as follows. When modeling the variation of the specific growth rate with the environmental factors like temperature, water activity, etc, the logarithm function is commonly used as a variance-damping link function. Therefore, if the standard error of fitting for this model is denoted by SE, then $\log p$ will be exactly SE. Note that if the natural logarithm of the responses were modeled then, of course, $\text{Ln}\, p = \text{SE}$.

In our experience, the amended accuracy factors of most predictive models for the specific growth rate (or doubling time) of viable count cultures are between 1.2 and 1.5, depending on the number of environmental factors in the model and on the range of those factors. That means that 10% to 40% additional error was generated compared with the 10% error resulting from calculation of the rate from a viable count growth curve. However, even with this additional error, the predictive models are extremely useful in food microbiology.

16.5 PROSPECTS

Models should be regarded as useful tools to assist decision making rather than substitutes for experience and knowledge of microbial responses. Users of models should be conversant with the manner in which the models have been produced, and their relevance to microbial responses in foods. Ideally, users should "validate" models themselves by limited challenge tests, or by comparison with historical data of microbial responses in the food commodities of particular interest.

Experience indicates that models of microbial growth developed in laboratory media and including no more than four controlling factors, usually pH, % brine (or a_w), temperature, and one other factor, generally offer a rapid, convenient, and reasonable "first estimate" of how foodborne bacterial pathogens will behave in many food systems. As larger quantities of data for a broader range of microbes covering more and more controlling factors (CO_2, nitrite, ethanol, organic acids, naturally occurring antimicrobials, etc) are accumulated, confidence that modeling is the most cost-effective way forward is likely to increase. This modeling approach has been applied successfully to bacteria, yeasts,[40] and molds.[33]

The relevance of models to growth of pathogens in foods should be checked carefully before predictions are used in commercial circumstances or for regulatory purposes. The least costly means of such checking is by comparison with independent data in the literature. To avoid costly and time-wasting duplication of effort, comparisons of model predictions and independent estimates of microbial responses should be accumulated (eg, in a database) to identify those circumstances where models can be relied upon, and those circumstances where they fail and, therefore, should not be used or should be further investigated. The accumulated database of comparisons should include all the common food commodities, and the processes applied to them (raw, cooked, fermented, dried, cured, etc). Currently, no institution or organization has come forward to coordinate and support a centralized database, and comparisons of models with values collected from the literature rests with those producing or using models.

Existing validated models give reasonable predictions of growth rates, but less valid estimates of lag times. This is understandable because the growth rate depends upon the environment in which growth is occurring and will increase to the maximum permitted by that environment (as determined by pH, a_w, and temperature). In contrast, the lag time is dependent on the prior history of the cells comprising the inoculum, and that condition has not been researched in sufficient detail to be embodied in current models. For instance, dramatic fluctuations in temperature are known to induce lag, but the quantitative relationship between the magnitude and rates of temperature fluctuation with time and the duration of lag induced have not been quantified. It is an important topic for research if models are to be more usefully employed in processing environments. Similarly, the effect on lag of changes in pH and a_w remain to be explored.

If there was general agreement on indices of model performance, comparisons of models would be facilitated.[70] As a general rule, models should be as simple as reasonably possible with the minimum number of coefficients. This so-called *parsimony* is vital when using models for predictions. The goodness of fit, how a model fits to observations, can, in principle, be improved infinitely by just adding more parameters to the model. A special case of this overparameterization is the application of third-order polynomials for growth rate models, as criticized in Baranyi et al.[7] Importantly, the more overparameterized the model, the greater the chance that it gives nonsense predictions, especially in regions where data are scarce. Predictions should always make "biological sense," and reflect the experience of microbiologists of the growth and death responses of organisms in foods.

While the potential consequences of overparameterization have been addressed, as indicated above, agreement on the definition of the usable domain of models is still under active discussion.[7] It has been proposed that this domain can be sensibly proscribed by, for example, the minimum convex polyhedron (convex hull) around the conditions under which data have been generated.[7] Extrapolation of the ranges of conditions to give predictions beyond the multidimensional space in which data that led to the model were accumulated decreases enormously the reliability of predictions, and to an extent that is impossible to quantify.

Kinetic and probabilistic models are already being combined[60] leading to estimates of both the rate of growth and the likelihood of it being achieved.

There are opportunities to advance predictive microbiology by applying instrumental methods, eg, impedance,[25] conductance,[41] indirect conductance,[24] turbidity,[22] gas chromatography,[8] gradient plates coupled with image capture and analysis software,[81] and gel cassette coupled with laser scanning.[13] However, it must be kept in mind that the measured responses using these techniques are not necessarily linearly proportional to the size (numbers) of the bacterial population, and, therefore, these models may not be comparable to models based on viable counts. Nevertheless, automated measurements can be useful to establish certain characteristic features of predictive models, such as growth–no growth boundaries, optimal values of environmental values, interactions between factors, etc.

Most currently available growth models would be improved, and more generally useful, if their ranges of conditions were greater, in particular covering the extreme ranges of conditions permitting growth.

Once a model has been validated for a particular food group, eg, meat products, so that predictions of growth closely mimic reports in the literature for the same environmental conditions, the models become useful guides to bacterial growth in those foods. Confidence intervals can be added to predictions,[46] but are often large, especially toward the extreme conditions of growth. Because lag time is a function of the prior history of the inoculum and of changes in environmental conditions, eg, changing temperature, models commonly overestimate the overall growth response. Although this is regarded as "failing safe," in that the estimate is a "worst case scenario," the value of models could be improved greatly by research effort being directed at understanding the quantitative relationship between changing conditions and the lag time subsequent to those changes. As an example, when temperature changes within the range of temperatures for growth, growth rate adjusts almost instantaneously to the new temperature. However, if the temperature exceeds the maximum for growth or falls below the minimum for growth, or even approaches those values, some additional lag is induced, and that is not currently taken into account in models.[6] New experimental approaches are required to correlate those changes with the growth response. Despite such limitations, models of thermal death and growth of pathogens are already proving useful in quantitative risk assessments.[88]

Whatever the experimental approach to developing models and comparing model outputs with values from the literature or with those from challenge tests, well-organized databases are essential. Commonly, the experimental data are collected and initially stored without critical evaluation ("database 1"). Critical examination commonly rejects part of the collected raw data, leading to "database 2." All, or part, of "database 2" may be used to develop a preliminary model, which often identifies the need for additional experimentation to consolidate or extend the model. The dataset, or subset of data, used to develop a model must be readily identifiable with it. Subsequently, even more data may be added to improve the model further. Each step needs careful documentation if datasets leading to intermediate and final models are to be retrievable.

Similarly, data compiled from the literature require careful supporting documentation if optimal use is to be made of them. Every measure of growth or death (specific growth rate, generation time, time to turbidity, D-value, etc.) must be supported by details of the experimental environment including the following: pH and the acid used, % brine or a_w and the humectant, temperature(s) and duration of the experiment, other preservative factors and their concentrations, gas atmosphere, the size of the inoculum, methods to recover the microbe(s), and any process that might affect the estimate, such as sudden change of temperature or pH from the subculture to the test conditions and any other changes that could lead to "injury" and lag being induced.

Predictive models began via purely empirical approaches, supported by statistical tools. Today, more and more mechanistic elements are used in their construction, in parallel to more and more advanced use of mathematical modeling and computational tools. The key to this development is the cooperation between microbiologists and food technologists on the one hand and mathematicians and statisticians on the other. In this chapter, some examples have been given to demonstrate this process. This can lead not only to better understanding of bacterial kinetics but also to more accurate predictions and, ultimately, safer and better quality food.

If "predictive microbiology" can be realized widely for thermal death, nonthermal death (survival), and growth conditions, food microbiology will advance immeasurably. Once a model has been validated in a product, it can be used at all stages of the food chain from harvesting, through production and processing, to distribution and retail sale. Modeling is already being incorporated into hazard analysis critical control point (HACCP) systems, product development, and quantitative risk assessment. Coupled with process engineering and knowledge of thermal properties of foods, predictive modeling will prove an increasingly powerful tool in the quest to optimize quality and safety.[74,91]

17.1 INTRODUCTION

Approximately 121 million metric tons of meat were produced by selected countries of the world during 1995.[122] China produced the greatest amount, 37 million metric tons. The United States (US) produced the second largest amount, 19 million metric tons, and beef and veal accounted for about 60% of the meat produced. In China the production focused on pork.

China and the US were forecasted to export 358 and 1,367 thousand metric tons of meat in 1997, respectively.[128] China was forecasted to import 3,000 metric tons of red meat, limited to lamb/mutton/goat, whereas the US was forecasted to import 1.3 million metric tons of all red meats. The largest exporters of red meats are Australia and the US with a total of 1.37 and 1.18 million metric tons in 1995, respectively, and 1.39 and 1.37 million metric tons for 1997, respectively. The largest importers of red meats are Japan, the US, and the Russian Federation with imports of 1.84, 1.28, and 1.08 million metric tons in 1995, respectively, and imports of 1.87, 1.34, and 1.27 million metric tons in 1997, respectively. Historically, meat has been shipped frozen but some of the newer technologies of thorough cleansing of carcasses, strict temperature control, and vacuum and modified atmosphere packaging have allowed for shipping of chilled, fresh meat, even in international trade.

The steps involved in the conversion of animals into meat (Figure 17-1)[129] include transporting the live animal from the production unit to the slaughter facility, then killing, skinning, eviscerating, washing, chilling, cutting, boning, and packaging. Pigs are not usually skinned so the steps differ in that the carcasses are scalded, dehaired, singed, and polished before evisceration, chilling, cutting, boning, and packaging (Figure 17-2). Live animals and the resultant carcasses are inspected for wholesomeness during this process. Wholesomeness means the meat resulted from healthy animals but does not imply freedom from spoilage nor potentially pathogenic bacteria.

Red meats that have been processed and cooked properly provide the essential amino acids, minerals, vitamins, and other nutrients for human nutrition. Microbial contamination of fresh red meat occurs mainly on the surface. The internal portions of the intact meat are usually free of spoilage or pathogenic microorganisms unless the slaughter animal had a septicemic condition or had been infected with parasites. Viruses associated with meat from slaughter animals, to date, have not posed a serious concern to the health of the consumer. Although molds and yeasts may be present, they are of less concern than the presence of bacteria; for prions see Chapter 57.

Both spoilage and potentially pathogenic bacteria are present on the surface of the slaughter animal and in the intestinal tract at the time of slaughter. Facilities and red meat become contaminated from these two sources during slaughter and processing. Personnel can be another source of contamination and cross-contamination. Additional contamination and/or microbial growth may occur during storage, distribution, and handling.

Initially, the surface microflora of red meat consist of a mixture of the microbes. If conditions are appropriate, both spoilage and pathogenic microorganisms may multiply on the surface. Measures taken by the food industry to reduce the number of microorganisms present on raw meat include the following: (1) procedures to reduce the initial surface contamination of carcasses, (2) prevention of cross-contamination during processing, (3) the use of methods for decontamination (cleansing) of meat, and (4) preservation and thermal processing.

Parasites can also be a serious problem. Antemortem and postmortem inspections, freezing, and cooking have been used for many years to prevent the transmission of parasites such as *Trichinella spiralis.* Less attention has been given to other significant parasites, such as *Toxoplasma gondii,* that may be present on pork, lamb, and other meats. If the meat is consumed without thorough cooking, these parasites may cause serious illness in humans, particularly in people who are immunosuppressed. In the healthy individual, *Toxoplasma gondii* can remain viable for years until health is challenged, at which time the parasite may reproduce and cause serious consequences, such as dementia. In females pregnant for the first time, the parasite can cause difficulties such as blindness or miscarriage of the fetus.

Extensive research effort has been expended on decontamination procedures to compensate for contamination that occurs during animal production, slaughter, evisceration, chilling, carcass separation, and packaging. Many of the proposed methods of decontamination are not totally effective (for example, the use of chlorinated washes, steam pasteurization, and ultraviolet treatment) or, as in the case of irradiation, are not generally acceptable to consumers. Greater attention is being focused, therefore, on methods to eliminate pathogenic microorganisms from carcasses, to reduce cross-contamination and extend the storage life of the meat.

17.2 COMPOSITION

Meat from slaughter animals consists of about 64% to 80% moisture, 16% to 20% protein (N × 6.25), 6% to 10% fat, and 1% ash (Table 17-1). The composition of the various muscles differs depending upon the muscle function and the proximity of adipose tissue, as well as animal species, breed, age, gender, and nutritional status. Younger animals typically have lower levels of deposited fat in their adipose sites. During maturation, fat is deposited within adipose tissue at a relatively rapid rate if adequate feed is available, whereas lean muscle is pro-

duced at a slower rate so that the fat-to-lean ratio increases. Moisture is retained at a relatively constant rate within the lean muscles but the moisture level of adipose tissue decreases as fat is deposited. The amount of connective tissue differs among the various muscles, and during maturation the amount of cross-linking within the connective tissues increases. It is not known whether connective tissue or the degree of cross-linking have any effect on microbial growth, although they may provide a physical barrier to the availability of nutrients. However, microorganisms attach readily to all physical components of meat such as chicken skin, chicken muscle connective tissue,[12] pork skin,[10,11] lamb and beef muscle,[10,23] and beef fat.[23]

Females deposit more fat than males and neutered males deposit more fat than intact males. Breed also affects the fat-to-lean ratio of carcasses. Dairy and dual-purpose cattle, for example the Guernsey, Limousin, and Charolais, have a lower or intermediate level of deposited fat than beef breeds such as Hereford or Aberdeen Angus. Genetic selection of pigs is responsible for significant changes in the muscularity and therefore conformation of the carcass and a drastic reduction in the amount of fat in the resultant meat. This selection of the very lean hogs has resulted in a temperament change of the pig, with some exhibiting a defect described as the "porcine stress syndrome" (PSS). This disorder is important to the pork industry because pigs sometimes die when subjected to stress, such as encountered during transport. PSS pigs may yield carcasses and meat that is pale, soft, and exudative (PSE). The PSE condition results from a rapid reduction of the meat pH post-slaughter. The lowered pH causes the proteins to approach their isoelectric points, thereby decreasing water-holding capacity and resulting in exudative meat.

The conversion of muscle of slaughter animals to meat involves the loss of available oxygen to the muscle cells, the utilization of available ATP, and the contraction of muscle fibers resulting in shortened sarcomeres, and in rigor mortis. Concurrently, there is the anaerobic utilization of some of the available glycogen, the production of lactic acid, and the reduction of the muscle/meat pH. The resolution of rigor mortis, interpreted on a consumer level as relaxation of the contracted sarcomeres, is due to sarcomere rupture at the "Z" bands and the activation of cathepsins, lipases, and other enzyme systems. None of these changes significantly influences the proximate composition of the resultant meat.

The composition of beef, pork, lamb, veal, chevon, and horse meat, as shown in Table 17-1, reflects very few species differences that could influence microbial growth. Adequate protein, moisture, and other nutrients are available in the meat of each of the species to support microbial growth. The limiting factors then are the availability of the nutrients, the ultimate pH, the water activity, the availability of oxygen, the storage temperature, and the levels and types of microorganisms on the meat surface.

The pH of muscle at slaughter approaches neutrality but usually is lowered to about 5.5 due to the breakdown of glucose to lactic acid. When an animal is stressed prior to slaughter, the glucose and glycogen levels in the muscles are lowered antemortem, and less lactic acid is formed postmortem. If the pH of beef muscle remains above 6.2 post-slaughter, the carcass is considered a dark cutter. The resultant meat will be dark, firm, and dry (DFD). This DFD meat supports microbial growth better than meat from unstressed animals[53] and will spoil more rapidly.[36] These authors suggested that because of the very low concentrations of glucose and glucose-6-phosphate in DFD meat, the spoilage bacteria utilize amino acids as substrates, and unpleasant by-products result. Egan and Roberts[36] indicated that the growth rates of pseudomonads, the predominant spoilage bacteria at refrigeration temperatures, are relatively constant within the pH range of 5.5 to 7.0.

17.3 SLAUGHTER/PROCESSING

17.3.1 Inspection

Current "Good Manufacturing Practices in Manufacturing, Packing, or Holding Human Food" describes the sanitary and processing requirements necessary to ensure the production of wholesome food.[15] The Food Safety and Inspection Service (FSIS) of the United States Department of Agriculture (USDA) evaluated 1,000 of the 6,400 meat and poultry establishments that they inspect and documented conditions that have previously been shown to result in high levels of contamination of meat with microorganisms. They have revised their "Sanitation Standard Operational Procedures" which outline standards of performance to obtain a wholesome product.[14] In addition, the UDSA has required the implementation of "The Hazard Analysis and Critical Control Point System" (HACCP) in inspected meat plants to improve the microbiological, chemical, and physical safety of meats.[127] The system is developed by plant management using guidelines established by the USDA. Under this preventative system, each plant determines steps in the process or the manufacture of the product where food safety problems might occur; then establish critical control points (CCP), critical limits, and corrective measures. They take corrective action when necessary, document and verify their action, and provide FSIS access to their records. Periodic testing for *Escherichia coli* and *Salmonella* spp. are part of the system. Additional information on HACCP is provided in Chapter 58.

Once slaughter animals have been transported to the abattoir, they are subjected to a pre-slaughter inspection.[14,121] Any dead, dying, diseased, disabled, or drugged (5D) animals are segregated. Carcasses from dead animals are denatured and not allowed for human consumption. Dying, diseased, disabled, or drugged animals undergo further evaluation and potential exclusion as meat for human consumption. Inspectors attempt to exclude meat of diseased animals from marketing channels and to minimize microbial contamination of meat. During antemortem and postmortem inspection, using subjective procedures such as visual appraisal and palpation, about 164,000 cattle (0.50%), 212,000 pigs (0.24%), and 13,000 sheep (0.28%) annually are excluded from marketing channels in the US, because of disease, unfitness, or adulteration.[119] Currently, research is under way to develop additional methods to detect specific disease conditions in the carcasses of slaughter animals and the resultant meat.

Unfortunately, slaughter animals are liable to be contaminated with fecal material. Such fecal material has been shown to contain *Salmonella* spp., *C. jejuni/coli*, and other pathogenic bacteria. These bacteria are not only in the intestinal tract, but also on the exterior of the slaughter animal. In 1994, the FSIS declared *Escherichia coli* O157:H7 an adulterant in ground beef, thus requiring that it must be excluded from such meat. In 1999, the FSIS proposed to extend the declaration of the bacterium as an adulterant if found in "non-intact" beef products such as mechanically tenderized, cubed, reconstructed, or injected products. In 1997, one company voluntarily recalled 25 million pounds of ground beef because illness caused by *E. coli* O157:H7 was traced back to their product. The resultant loss of confidence and financial drain caused the plant to be closed. FSIS is faced with the enormous task of excluding from market channels those carcasses that have not been cleansed adequately to remove the potentially pathogenic bacteria. Most slaughter animals have some degree of surface fecal contamination and therefore are exposed to pathogenic bacteria. However, dressing procedures significantly decrease microbial counts on the carcass.

17.3.2 Residues

Antibiotic and chemical residues, though of concern to the consumer, are rated below microorganisms in importance by food scientists. Rapid screening tests are in use in slaughter establishments for detecting some residues. Antibiotic residue detection methodologies based on the inhibition of bacterial growth require close scrutiny because some pork carcasses contain naturally occurring bacterial inhibitors that result in false positives in such screening tests.[87]

17.3.3 Control

The US FSIS has published guidelines for the application of HACCP to the processing of muscle into meat.[127] Figure 17-1 provides one example of a HACCP flow chart for the slaughter, fabrication, and packaging of cattle, whereas Figure 17-2 provides similar information for pigs. Each of these slaughter animal groups is subject to surface contamination with dung as a result of farm practices and stress during live transport, holding, and slaughter. Attempts are under way to limit the stress in livestock during shipping and holding prior to slaughter because stressed animals are more apt to shed pathogenic bacteria such as *Salmonella* spp. and can lead to contamination of greater numbers of animals. Efforts have been under way for a number of years to present animals for slaughter in a humane manner that minimizes animal stress and injury.[50–52]

Production practices are under review to try to minimize fecal contamination of livestock. Greater attention is now being directed toward eliminating fecal material from the surface of animals presented for slaughter. Pre-slaughter washes, and post-slaughter washes and hair removal, are being evaluated as a means of reducing the potential for contamination of the carcass during hide removal. However, carcasses from beef that had considerable quantities of dung on their hides have been shown to maintain higher levels of microbial contaminants than cleaner animals, even if the dirty animals were processed using a slower line speed and with greater care in slaughtering procedures.[99]

Feed withdrawal, before the transport of live animals to slaughter facilities, has the advantage of lowering gastrointestinal tract contents, reducing the incidence of viscera rupture and, therefore, lowering the risk of pathogen contamination of carcasses.[86]

Throughout the slaughter establishment, walls should be placed between operations to separate areas with high airborne microbial populations from those with fewer numbers. Kotula and Emswiler-Rose[71] found 2 to 3 Log_{10} aerobic cfu per 0.028 m^3 in the various processing rooms of a commercial pork processing establishment. In commercial beef processing establishments, Worfel et al.[132] reported 1.66 to 3.17 Log_{10} aerobic cfu per 0.028 m^3 in hide-on areas, with the lowest counts seen in a plant with a serpentine slaughter line. In hide-off areas counts ranged from 0.52 to 2.08 Log_{10} aerobic cfu per 0.028 m^3. Air filters should be utilized to reduce these counts, especially in locations where trimmed meat is being fabricated. Aerosols should be controlled throughout processing. Simple operations such as carcass spraying, carcass splitting, and clean up significantly increase the number of airborne microorganisms.

Slaughtered cattle, sheep, goats, and horses are skinned whereas most pig carcasses are scalded, dehaired, singed, and polished before evisceration. Potentially pathogenic bacteria can be found in fecal material on the surface of the slaughter animal and in its intestinal tract. Particular care is required for cattle, sheep, goats, and horses during skinning, head and shank removal, and bagging or tying of the bung to prevent fecal contamination of the carcass. Zink[133] reported that the use of steel plugs chilled in liquid nitrogen and inserted into the bung was an effective alternative to tying.

After slaughter, hogs are usually scalded in water between 60° and 70°C for 5 to 7 minutes for hair removal, rather than skinned (Figure 17-2). Bacteria that are potentially pathogenic to humans have been shown to accumulate in scald water and its use has been criticized.[59,112] Scalding allows microbially contaminated water to enter the carcass via the nose and mouth, and sticking point, and to be transferred to the lungs, circulatory system, organs, and musculature.[59,112] Scalding pigs hanging in the vertical position resulted in less internal contamination than combined scalding/dehairing. The use of steam scalding has been suggested.[133] Skinning of pork carcasses is more economical than scalding,[60] but the industry continues to have a market for hams with skin.

After pork carcasses are scalded, they are singed to remove any remaining fine hairs. Singeing has been reported to effectively reduce the bacterial numbers on the skin surface in some cases,[24,47,89] but increase it in others.[47,89]

The carcasses are then polished with brushes to remove charred portions of the epidermis (blackscraping); this process may spread bacteria over the carcass.[89,96] Ice blasting, ie, impelling small ice crystals against the singed carcass surface, was reported to remove the carbonized layer of the rind effectively and to cost about the same as using automated polishers.[133]

Pork carcasses that were brushed before scalding had higher counts of aerobic bacteria than nonbrushed carcasses; however, this increase was not apparent until after singeing and blackscraping.[96] The researchers' explanation is that the brushes break and lacerate the carcass skin, thereby allowing microorganisms to enter the skin during scalding and be protected from the heat of singeing. Blackscraping contributes further to contamination. Although there was no significant difference after chilling between brushed and nonbrushed carcasses, the authors strongly discouraged the use of prescalding brushing.

Though not currently utilized, postexsanguination chemical (sodium sulfide) dehairing of beef carcasses has been reported to reduce visual contamination; however, it did not reduce the overall bacterial load.[103] The potential commercial dehairing procedure calls for dehairing after stunning, but before bleeding. Delay of bleeding after stunning may be considered inhumane. Dehairing after bleeding may contribute to chemical contamination of edible portions of the carcass.

The carcass is trimmed to remove visible dirt, lesions, and visible bruises. If the viscera are ruptured during evisceration, further trimming and washing is needed. The incidence of ruptured viscera from hogs was shown to be reduced from 1.5% to 0.5% by increasing the rest period of the live animal after transport to 4 hours instead of 2 hours.[86] Cross-contamination between carcasses can be reduced if operators wash their hands between carcasses and if knives are decontaminated.[18] Efforts are under way to more completely automate evisceration with the expressed goal of minimizing cross-contamination during that process.[133]

17.3.4 Carcass Washing

The regulatory agencies, the meat industry, and the scientific community have directed much attention to cleansing procedures for reducing the number of bacteria on each meat carcass, regardless of species. Suggested procedures include treating carcasses with cold water, hot water, steam, chlorinated water (20 to 50 ppm), a 1% to 3% acetic, lactic, or citric acid solution, tripolyphosphate, potassium sorbate, ozone, irradiation, and others. A number of these procedures are not approved, and others are not feasible because of economic, palatability, or public health considerations.

Pressurized cold water, or water heated to 82°C, is effective in removing surface bacteria from carcasses. It effectively removes dirt that may have fallen onto the carcass during skinning. Water at 82°C can be utilized as a bactericidal treatment after evisceration. A series of warm water (57°C) and hot water (95°C) washes under pressure reduced the initial counts of 5 Log_{10} by 3.7 logs, 3.8 logs, and 3.3 logs, for *E. coli* O157:H7, *S. typhimurium*, and hydrotolerant coliforms, respectively.[13] The authors suggested that the use of coliform counts may be possible for verification of the effectiveness of hot water treatments used as critical control points (CCPs) in HACCP.

Steam treatment of beef carcasses has been reported to be more effective than trimming, 35°C water washing, or hot water/steam vacuum spot cleaning, in reducing counts of *E. coli* O157:H7, *S. typhimurium*, and *Listeria monocytogenes* on inoculated carcasses.[95] Steam treatment followed by spot cleaning can give a reduction of 4.2 to 5.3 Log_{10} cfu cm^{-2}.[95] Steam pasteurization of naturally contaminated carcasses, within a commercial slaughter facility that used knife trimming, steam vacuum spot cleaning, and final carcass washing, reduced populations of aerobic bacteria, *E. coli*, coliforms, and Enterobacteriaceae more than knife trimming, steam vacuum spot cleaning, and final carcass washing alone.[92] Whereas 15 of 79 cow carcasses and 11 of 81 cattle carcasses initially had surface counts of 0.6 to 1.5 Log_{10} cfu cm^{-2} of *E. coli*, none of the carcasses had viable *E. coli* (detection limit of 0.6 cfu cm^{-2}) after 6 or 8 seconds of steam pasteurization treatment.[92] One major beef company in the US has installed steam treatment units in each of their establishments. Steam, hot water spray washes, and a steam vacuum treatment of beef and sheep carcasses will decrease bacterial populations,[25,26,28] and could reduce the amount of trimming necessary.[25] Gill et al.[48] reported the bacterial numbers from randomly selected polished pork carcasses washed with 85°C water for 20 seconds to be 1.1 Log_{10} cm^{-2} for the loin-lumbar region, 0 for the loin-thoracic region, 1.0 Log_{10} cm^{-2} for the foreleg, and 0 for the belly, whereas the counts for the unwashed carcasses ranged from 2.4 to 3.3 Log_{10} cm^{-2}.

Beef carcasses and the resultant meat are subjected to the possibility of cross-contamination from the time the hide is removed until the retail cut has been packaged. Cutter et al.[20] hypothesized that if a carcass is treated with dry heat, such as 400°C for 15 seconds (administered with a propane forced-air heater), the surface connective tissue will shrink, become dehydrated, and may affect attachment of surface bacteria. Carcasses treated in this manner immediately after skinning might be less subject to surface contamination during other handling procedures. To test this concept, beef desiccated in that manner was then inoculated with feces containing aerobic spoilage bacteria (6.5 Log_{10}), *L. innocua* (4.0 Log_{10}), *C. sporogenes* (3.6 Log_{10}), *S. typhimurium* (2.6 Log_{10}), and *E. coli* O157:H7 (3.3 Log_{10}) to simulate gross contamination. The beef was then washed with water (125 psi, 35°C, 15 seconds) and desiccated (400°C, 30 seconds). This treatment reduced the aerobic count by about 3 Log_{10} and the bacteria mentioned above were reduced to undetectable levels of less than 1 cfu cm^{-2}. In the same study, a water wash (125 psi, 35°C, 15 seconds) alone on unheated carcasses reduced the numbers of each of the test bacteria by at least 2 Log_{10}. The authors conjectured that the final heat treatment raised the temperature of the water adhering to the beef surface to >65°C, thereby destroying the bacteria. Use of 300°C instead of 400°C minimized discoloration of the surface of the carcass and reduced desiccation without decreasing the effectiveness of the process.

Chlorine has been used in the dairy, flour, water, and other industries to destroy bacteria. Used properly, it is also effective in reducing the numbers of viable surface bacteria on carcasses. The bactericidal effectiveness of chlorine sanitizers is dependent upon the type and concentration of the chlorine compound used, pH, temperature, contact period, type of microorganisms, and presence of organic material.[5]

Organic material, such as lean muscle, adipose tissue, and serum albumin, will deplete aqueous chlorine levels.[77] Therefore, chlorine solutions need to be carefully monitored to avoid depletion, while staying as close to the legal maximum, to ensure effectiveness. In the US, the maximum chlorine level is usually 20 to 50 ppm.[125]

Of the four sources of aqueous chlorine, which include (1) gaseous chlorine bubbled through water, (2) chlorine dioxide, (3) calcium hypochlorite dissolved in water, and (4) chlorine generated electrolytically from sodium chloride, the electrolytically generated chlorine solutions appear to be most practical and effective, but the use of sodium or calcium hypochlorite may be more economical. Gaseous chlorine may be incorporated into water to a level of about 25 ppm but, depending on the water temperature, the chlorine may not be bound and may escape into the room. Such gaseous chlorine is not only irritating but is also deadly.

In a study where beef forequarters were washed with water, sodium hypochlorite, calcium hypochlorite, or chlorine dioxide, calcium hypochlorite was shown to be a little less effective than the sodium hypochlorite solutions generated electrolytically from brine, but the difference was not very great.[38] Chlorine dioxide was most effective against psychrotrophic bacteria at about 50 ppm (1 Log_{10} reduction in count after 24 hours), whereas plain water and calcium hypochlorite at 50 ppm caused no reduction in numbers of viable psychrotrophic bacteria (Table 17-2).[38] Reductions in aerobic counts were

greatest when the chlorine solution was adjusted to a pH of 6 to 7 with acetic acid and the chlorine concentration was increased to 200 ppm (Table 17-3).[63] Lowering the pH to 4 or 5 decreased the effectiveness of the wash. A high-pressure wash of 24.6 kg cm^{-2}, which used 4 L to wash a beef forequarter for 30 seconds, was more effective than a wash at 4.2 kg cm^{-2}, which used 1 L. Wash water at 51.7°C yielded an average Log_{10} reduction of 3.2 compared with 2.3 for wash water at 12.8°C. The effects of pH and wash water temperature were overshadowed by the effectiveness of high-pressure washing, which frequently resulted in a reduction of the bacterial numbers to less than two per square centimeter (Table 17-3).[63]

Research by Emswiler-Rose and Kotula[41] on the inhibition of pure cultures of bacteria with chlorine indicates that use of 20 to 50 ppm chlorine, which represents the level usually allowed by the US FSIS, may have less than the desired effect on some bacteria, including *Salmonella* spp., *B. cereus*, *E. coli*, and *Y. enterocolitica* (Table 17-4). Admittedly, in that study, there was binding of some of the chlorine to the agar, making it unavailable to inhibit microorganisms. However, chlorine also binds with organic material, such as lean and adipose tissue, during usage in slaughter and processing facilities. Available chlorine is reduced most readily by lean muscle, then by agar, and least by adipose tissue,[77] therefore, the agar plates used by Emswiler-Rose and Kotula[41] offered a reasonable approximation of how the chlorine will act in a slaughter/processing situation. Chlorine solutions are used, and approved by FSIS, based on initial concentration, that is, before contact with meat.

Although chlorine has been used to control microbial growth on animal tissues for over 40 years in the US, questions persist concerning the safety of chlorine treatments of meat. Fidler[43] reported that hyperchlorinated water (25 to 30 ppm) suppresses macrophages, may compromise host resistance against neoplasms, and may result in anomalies in animals. Chlorine in the presence of humic substances can form carcinogenic compounds. Some fatty acids and possibly some amino acids of meats, react with aqueous chlorine.[62] Chlorinated oleic acid decreased absorption in the digestive tracts of rats from 93% to 76%.[19]

The use of organic acids has been studied extensively and has been recommended by numerous scientists for the reduction in colony-forming units on carcasses.[2,3,108,131] However, organic acids, such as acetic and lactic, caused a bleaching of the meat surface in experimentally treated retail cuts without adequately reducing bacterial counts.[76] In many published reports the reduction is about 90%. From an economic standpoint, one may question the logic of using organic acids if the resultant reduction is only about one logarithm when the total count is about 5

or 6 logarithms. In other studies, lactic or acetic acid (1.5% or 3%) or 12% trisodium phosphate, which initially reduced pseudomonads by less than 1 Log_{10}, then provided a residual inhibitory effect so that whereas bacteria on the control samples and water-washed samples increased to 5 Log_{10} in 19 days of vacuum packaging, the samples treated with the antimicrobials did not increase in number.[27] Of equal interest, the antimicrobials reduced numbers of *E. coli* O157:H7, *L. innocua*, and *C. sporogenes* by about 3 Log_{10} and inhibited the growth of these bacteria during 19 days of vacuum packaged storage.[28] There appeared to be little difference between using 1.5% and 3% of the antimicrobials, but application method appears important. Previous literature[30] reported that *E. coli* O157:H7 on beef carcasses was exceptionally tolerant to this treatment. Citric, acetic, or lactic acid at concentrations of 0.5% to 1.5% applied at 22° and 55°C resulted in a reduction of less than 0.5 Log_{10} of *E. coli* O157:H7. Trisodium phosphate was not as effective in reducing numbers of *L. innocua* as were acetic and lactic acid. A soapy mouth feel has been attributed to meat treated with trisodium phosphate. Repeated pressured water washes might be more efficient and would not add to consumers' apprehension about the use of chemical additives but the residual inhibition of growth would not be evident.

The use of potassium sorbate has been studied for the control of bacteria on fresh red meat.[113] When studied for the control of bacteria on bacon, it caused prickly mouth sensations and "chemical"-like flavors,[6] swelling of the hands of individuals handling the treated meat, and asthma-like symptoms during cooking and after consumption.[55] There is no reason to expect dissimilar results if potassium sorbate were used on red meats. Additionally, potassium sorbate, in combination with nitrite (from vegetables, cured products, or saliva) and heat can form mutagenic compounds.[55]

17.3.5 Irradiation

Irradiation of pork, using a minimum dosage of 0.3 kGy and a maximum dosage of 1.0 kGy, has been authorized in the US for the control of *Trichinella spiralis*.[93] A minimum of 1.5 kGy and a maximum of 3.0 kGy are allowed for the control of pathogenic bacteria on poultry. The use of irradiation for the destruction of bacteria on red meats has been approved by the Food and Drug Administration but dosage levels have not yet been specified by the USDA. It is recommended that any irradiation treatment should be such that it will allow some competitive bacteria to survive and help control the germination of spores of *C. botu-*

linum, which could result in toxin production.[93] The same concerns about the potential for spore germination have prevented the use of anoxic environments, including modified atmosphere packaging (MAP) or vacuum packaging for irradiated poultry. Some countries other than the US have approved irradiation of red meats at maximum doses of 3–7 kGy.

It has been estimated that irradiation of a pork carcass would cost 3 to 8 dollars, in addition to the cost of transporting the carcass to and from the irradiation facility. If the pork carcass is to be irradiated with gamma rays, it is desirable to freeze the pork first to minimize the off-odors and off-flavors that result from the irradiation at dosages of 1 kGy and higher. Under suitable conditions, freezing of pork destroys viable *T. spiralis*. The temperature at which pork needs to be frozen to minimize off-odors and off-flavors during irradiation (–60°C) is lower than that required to inactivate *T. spiralis* (–37.2°C for 0.5 hour). In the US, a pork certification program exists, which ensures that the raw pork has received a proper freezing treatment (Tables 17-5 and 17-6).

The irradiation dose that is effective against spoilage bacteria must be increased to control potentially pathogenic bacteria of importance, and higher doses are required for frozen red meats than for chilled meat.[93] Unfortunately, increased dosages cause an increase in development of off-flavors and odors. Although irradiation is authorized for the control of *T. spiralis* in pork and for the control of pathogenic bacteria in poultry, its use is very limited in the US. Regulations require that any such irradiated meat and poultry be labeled as having received that treatment.

In the US consumers have not yet accepted irradiation of meat and poultry. Those consumers who show interest in irradiated meats seem to have the incorrect perception that these products would be sterile, and therefore, the consumer would not need to be concerned with time/temperature abuse of these products. This is an extremely dangerous attitude because meats irradiated at the currently accepted level are not sterile, and could be potentially hazardous if handled improperly.

17.3.6 Fabrication

After a beef, pork, or lamb carcass has been eviscerated and washed, it is customarily chilled to below 4°C within 24 hours. This reduces the rate of growth of surface bacteria, slows enzymatic activity,

and decreases biochemical reactions within the meat. A number of disadvantages are associated with the chilling of the intact carcass. Chilling occurs much more rapidly in smaller pieces, such as primals and trimmings, than in deep muscles of the intact carcass. Removal of excess fat and bone before chilling could save considerable energy in terms of total refrigeration. In addition, "breaking" (cutting into primal cuts) a chilled carcass requires more energy than breaking a hot carcass because chilled meat is less flexible. No differences of any practical significance were found between aerobic plate counts, coliforms, or *E. coli* in ground beef fabricated from trimmings that were hot-boned (excised from the carcass within 2 hours postmortem) and trimmings that were cold-boned (removed after 24 hours chill) at 3°C.[40,65] It was necessary to add CO_2 snow to the hot-boned trimmings during the fabrication of the ground beef to reduce the meat temperature rapidly and preclude smearing of the fat during grinding. Hot-boned meat can be distributed to the consumer faster.

In the US, graded beef usually originates from breeds such as Hereford or Aberdeen Angus cattle specifically raised for their meat. Hot-boning of beef carcasses would occur after eviscerating and washing but before chilling. There are disadvantages to hot-boning because it can result in toughening of the meat and changes in the appearance of the meat create difficulties in grading. This problem can readily be resolved by electrical stimulation of the carcass immediately after evisceration and washing. When properly stimulated, the carcass shows a rapid drop in pH (Figure 17-3), which prevents shortening and toughening of the meat.

One of the greatest obstacles that must be overcome during the breaking of carcasses is the cross-contamination between carcasses and from equipment that occurs when quarters, primals, and subprimals are placed on trays or conveyor belts.[65] From a bacteriological standpoint, the primal should be placed into a package as soon as it is excised from the carcass.

More than 50% of the beef sold in the US is sold as ground beef. The grinding and mixing involved in its manufacture distribute bacteria normally found on the meat surfaces throughout the entire product. The bacteriological quality and shelf life of ground beef depend upon the bacteriological quality of the ingredients, sanitation, and temperature during processing, type of packaging, and time and temperature of storage. This was demonstrated by a study in a centralized meat packaging and distribution center that prepared about 18,000 kg of ground beef daily under federal inspection.[17] Table 17-7 shows the level of selected bacteria on the ingredients of the ground beef and the final product. Surface bacterial counts were higher on the cow beef than on trimmings or flank meat. The meat juices in the bottom of the stainless steel holding bins also contained inordinately high bacterial counts. As the bins were filled, the juices were squeezed from the meat, washed over the surface of other pieces, and provided a good substrate for growth. The bacteriological quality of cow beef and expressed juices was significantly correlated with the bacteriological quality of the resultant ground beef (Table 17-7).[17] The addi-

tion of chilled plate cuts of beef, which had greater numbers of bacteria than the other ingredients, had an important influence on the bacteriological quality of the ground beef.[70]

17.4 INITIAL MICROFLORA OF FRESH RAW MEATS

17.4.1 Spoilage Bacteria

The important spoilage bacteria of fresh meat include *Pseudomonas*, *Acinetobacter/Moraxella*, *Aeromonas*, *Alteromonas putrefaciens*, *Lactobacillus*, and *Brochothrix thermosphacta*.[21,79] Emswiler et al.[39] cited literature that reported that ground beef may contain extensive bacterial populations. Although beef color change from red to brown can be indicative of microbial growth,[100] some bacteria can reverse this change. *Brochothrix thermosphacta*,[7] a fluorescent strain of *Pseudomonas* isolated from fresh meats,[42] and *Staphylococcus carnosus* and *Staphylococcus caseolyticus* isolated from fermented meats[88] can all cause reversion of the brown-colored metmyoglobin to the more desirable color of oxymyoglobin in meat products that showed sensory spoilage.

Lambert et al.[79] described the substrates used for growth and the metabolic by-products of major spoilage microorganisms (Table 17-8). Typically, spoilage bacteria use glucose, amino acids, and lactic acid, in that order, to support their growth. The availability of these nutrients to bacteria is restricted to some degree by connective tissue and adipose tissue, which envelope muscle, but the nutrients become more readily available when muscle is cut.

The major end-products of metabolism of common meat spoilage organisms are sulfides, amines, acetic acid, lactic acid, isovaleric acid, isobutyric acid, esters, and nitriles. During prolonged storage of beef products under vacuum, bacterial proteolysis and decarboxylation can release pressor amines, such as tyramine.[107] Such amines may be toxic to individuals taking monoamine-inhibiting drugs. A thorough review of the chemistry of spoilage of meat stored aerobically and that stored under vacuum was presented by Dainty et al.[22]

The growth characteristics of the spoilage bacteria of meat depend upon initial flora, level of contamination, storage time, and temperature.[4] In a classic study, Ayres[4] demonstrated that pronounced off-odor developed on the surface of meat when the microbial count reaches about 10^7 cm^{-2}, and slime developed at about 10^8 cm^{-2} (Figure 17-4). The onset of off-odors has been reported at 1 to 2 × 10^6 organisms cm^{-2}.[4,37,78] Meat with a greater initial level of contamination spoiled more rapidly and spoilage occurred more rapidly at higher temperatures (Figures 17-4 and 17-5). To extend the shelf life of meat, keep it clean, covered, and cold.

17.4.2 Potentially Pathogenic Bacteria

The important potentially pathogenic bacteria that have been linked to fresh red meat include *Salmonella* spp., *Escherichia coli* O157:H7, *Listeria monocytogenes*, *Clostridium botulinum*, *Staphylococcus aureus*, *Yersinia enterocolitica*, *Clostridium perfringens*, *Campylobacter*, *Aeromonas hydro-*

phila, and *Bacillus cereus*.[79,84,85] The USDA sampled approximately 2,000 steer/heifer, 2,100 cow/bull, and 2,100 pig carcasses, in a nationwide microbiological baseline data collection program (Tables 17-9 and 17-10). The incidence of the tested organisms on cow/bull carcasses was coliforms, 32%; *E. coli*, 16%; *S. aureus*, 8%; *C. perfringens*, 8%; *L. monocytogenes*, 11%; *C. jejuni/coli*, 1%; *Salmonella*, 3%; and *E. coli* O157:H7, 0%.[123] Rice et al.[98] reported an incidence of 3.4% for *E. coli* O157:H7 in fecal material of 205 cull dairy cows from 19 herds sampled on the farms, and 3.9% positive when 103 cull cows from 15 herds were sampled at slaughter. When 89 cull cows were sampled both on the farm and at slaughter, 3.3% were positive at the farm, 2.2% at slaughter, and 2.2% at both locations. The fact that one study isolated no *E. coli* O157:H7 on carcasses, whereas another study did find the organisms in the fecal material, emphasizes herd to herd variability and suggests that efforts are being taken during slaughter operations to minimize fecal cross-contamination. That cross-contamination of facilities and product does occur has been demonstrated (Table 17-11).[81] In a study of 30 dressed lamb carcasses in Spain, Sierra et al.[105] described isolating *Salmonella* (10%), motile aeromonads (33%), *Yersinia enterocolitica* (20%), *Campylobacter* (0%), and cold-tolerant *E. coli* (57%). None of the *Y. enterocolitica* were presumptive virulent and the O157 antigen was not detected in any of the *E. coli* isolates. Sampling of 50 pigs at a USDA-inspected slaughter establishment resulted in finding 2 with cecal contents, and feces were positive for serotype O:5,27, biotype 3 of *Yersinia enterocolitica*, whereas all other pigs were negative for pathogenic serotypes.[75] Other chapters in this book deal more specifically with pathogenicity, the growth characteristics, and public health importance of these potentially pathogenic bacteria.

Differences in plant operations as well as sampling procedures may influence bacterial results. Twenty samples of carcass, clod, and lean trim were taken in each of two plants slaughtering steer and heifers.[61] All samples were negative for *E. coli*

O157:H7 and *Salmonella* spp. All samples were negative in one plant sampled for *C. jejuni/coli*. In the second plant, 27.5% of the carcass samples had detectable counts of *C. jejuni/coli* (greater than 10 cfu cm^{-2}), whereas the clod and trim had none. Five percent of the carcasses, 5% of the clod, and 8% of the trim samples had more that 10 cfu cm^{-2} or g^{-1} of *C. perfringens*. Twenty-one of 40 carcass samples and 15 of 40 clod samples had more than 100 cfu cm^2 or g^{-1} of coliforms. Coliforms and *E. coli* are indicators of fecal contamination, thus suggesting that improved sanitation might be helpful. The objective of the study[61] was to try to standardize sampling procedures to be used throughout the meat industry. Without standardization, results such as those presented by Karr and the USDA are of interest and provide a baseline but cannot be considered indicative of conditions in other establishments. Carcasses from cull cows, used for manufacturing ground beef, differed in incidence and counts of coliforms and *E. coli* among the six breaking plants which were sampled.[49] In plant A, 12 of 24 carcasses had detectable coliforms, and 7 of 24 carcasses had detectable *E. coli*, whereas in four of the other plants, 23 or more carcasses out of 24 sampled had detectable coliforms and *E. coli* present (detectable level of 1 cfu g^{-1}). The estimated values for the Log_{10} mean numbers of *E. coli* and coliforms was less than 1.0 for plant A but ranged from 1.2 to 3.0 for coliforms and 0.7 to 2.6 for *E. coli* in the other five plants sampled.[49]

When briskets and ground beef were examined from 547 slaughter establishments in the US, no association was found between *Salmonella* contamination and slaughter volume.[56] Brisket contamination with *Salmonella* was 0.9% of 1,836 heifers,

1.1% of 1,239 bulls, and 5.0% of 397 calves, when the sample size was 25 g. When the sample size was 100 g the incidence was 1.2% of 1,607 heifers, 3.0% of bulls, and 7.9% of calves.[56]

Whereas it would be expected that the slaughter/processing procedures will result in a decrease in microbial contamination, an evaluation of cow carcasses in three plants showed an increase in fecal coliform counts in two of the three plants as the carcasses proceeded from dressing to trimming/washing, refrigeration, and cutting.[16] To obtain microbiological baseline data for ground beef, the USDA evaluated 563 samples. They did not find any *E. coli* O157:H7 (Table 17-9). Doyle and Schoeni[29] isolated *E. coli* O157:H7 from 3.7% of beef, 2.0% of lamb, and 1.5% of pork samples from retail stores in Wisconsin. Similar retail meats from Alberta, Canada, yielded isolates from 31% of the beef and 7% of the pork samples.

The incidence of *C. jejuni/coli* in meats at retail was as follows: pork chops, 5%; beef flank, 4.7%; ground beef, 3.6%; and stew lamb, 8.1% in a countrywide survey in the US involving 1,800 red meat samples.[111] A survey of 1,077 retail samples in the

Source: Adapted with permission from A.A. Mafu et al., The Incidence of *Salmonella, Campylobacter,* and *Yersinia Enterocolitica* in Swine Carcasses and the Slaughterhouse Environment, *Journal of Food Protection,* Vol. 52, pp. 642–645, © 1989, International Association of Milk, Food and Environmental Sanitarians, Inc.

United Kingdom (UK), evaluated for *C. jejuni/coli/laridis,* showed an incidence of beef, 23.6%; pork, 18.4%; lamb, 15.5%; liver, kidney, heart (all species), 47%.[44] Roberts et al.,[101] sampling ground beef from three supermarkets, three intermediate-sized stores, and three small family butchers in the UK during warm and cool weather found no significant or important store or seasonal effects. They reported that of their 162 samples, the mean Log_{10} count was 4.6 for Enterobacteriaceae, 2.46 for fecal streptococci, 2.6 for presumptive coliforms, 0.63 for *Clostridium perfringens,* and 0.5 for *S. aureus.* These studies to provide baseline data of red meats at retail demonstrated great variability in incidence but confirmed that pathogenic bacteria are present in the world's meat supply at the retail level.

Differences in reported incidence of pathogens are dependent on animal class (ie, cows, steers, heifers, bulls, calves), animal health, production practices, season, weather, transport and handling methods, slaughter and processing, microbiological methods (sampling, transport, holding, enrichment, media, incubation), statistical evaluation, and scientific interpretation of the data. Although *Salmonella* were detected in the USDA Microbiological Baseline Data Surveys,[118,123,124,126] the serotypes present may not have been pathogenic. Even with the 1% incidence of *C. jejuni/coli* in those surveys, one does not know the virulence of the strains, thus the actual risk to the consuming public cannot be adequately defined from these baseline incidence data.

In developing countries lacking adequate refrigeration facilities, the relative importance of the mesophilic microorganisms will be paramount compared with the psychrotrophic microorganisms that would predominate on refrigerated meat. This is not to say that one is more apt to become ill from the meat that has not been refrigerated, but additional care is indicated.

Typically, when refrigeration is lacking, animals are slaughtered in the early morning and the carcass is not cut up until a customer is prepared to buy some meat. Cuts are then sold sequentially from one end of the carcass to the other, thus, the exposed surface of the meat is kept to its smallest area so that contamination is minimized. Additionally, the meat is cooked soon after purchase so the bacteria do not have as much time to multiply.

17.4.3 Molds and Yeasts

The six genera of molds most readily isolated from slaughter animal carcasses or cuts include *Thamnidium, Mucor,* and *Rhizopus,* which produce white mycelia on beef; *Cladosporium,* which is associated with black spot; *Penicillium,* which produces green growth; and *Sporotrichum,* which produces white spot. The presence of mold is usually associated with dry meat that has an acid pH. In fresh meat, bacterial growth inhibits molds that might be present. The white mycelia of *Thamnidium* on aged beef has been considered desirable by some in the industry because beef aged 2 to 4 weeks at about 4°C has a particular "nutty" flavor, is very tender, and is preferred by some people.

The yeasts that have been isolated from meat include the genera *Candida, Torulopsis,* and *Rhodotorula.* Although sometimes present, these yeasts have not been a problem to the meat industry because when their requirements for growth are encountered during the storage of meat, bacterial spoilage occurs before the yeast numbers become a matter of concern.

17.4.4 Viruses

Fortunately, viruses that cause disease in slaughter animals are usually unable to cause disease in humans. Contamination by a food handler can result in transmission of viruses on meat. Enteric viruses that are transmitted by the fecal-oral route are discussed in Chapter 52. Viruses that cause hepatitis B, genital herpes, and AIDS are not believed to be transmissible by meat.

17.4.5 Parasites

Parasites of importance to the meat industry include nematodes like *Trichinella spiralis*, cestodes like *Taenia*, and protozoa like *Toxoplasma gondii*. Each of these parasites can be destroyed easily by proper cooking of the meat.

Trichinella spiralis

Although the incidence of *T. spiralis* in meat has been reduced significantly throughout the world, it is still liable to be present. In the US, one estimate suggests that one in a thousand hogs contain trichina.[58] Bears, rodents, wild pigs, hyenas, and other carnivorous animals also contain the parasite.

Many countries require mandatory inspection of pork carcasses for the presence of *T. spiralis*. In the US inspection by the pooled digestion technique or freezing the pork to destroy the parasite is required only if the meat is to be used in products that will not receive a thermal or curing treatment adequate to destroy the trichinae.

Current methodology for the detection of *T. spiralis* larvae in pork carcasses utilizes samples of the diaphragm muscle or tongue tissue. The diaphragm contains the second greatest number of larvae and is used most frequently because it is readily excisable and is of little economic importance. Sampling of the tongue, which has the greatest number of larvae, would potentially result in a defect that could reduce its value.

The USDA FSIS requires a minimum of 5 g of diaphragm muscle or tongue tissue, or a minimum of 10 g of other skeletal muscle tissue for the pooled digestion technique for detecting *T. spiralis* larvae in pork.[14] Under the assumption of the completely random series or Poisson distribution, 5 g samples (Figure 17-6) are expected to detect 99.3% of the carcasses with a larval density of 1 per g of muscle from the pillar of the diaphragm (Crus muscle). The Council Directive No. L 26/67 of the European Union (EU)[35] authorized the use of a number of sampling techniques including a pooled sample consisting of 100 samples of 1 g so that 100 carcasses can be evaluated simultaneously.

In both descriptions of sampling procedures (FSIS and EU), the various anatomical portions of the diaphragm muscle are assumed to contain a uniform distribution of *T. spiralis* in infected carcasses. However, Kotula et al.[72] evaluated five identifiable parts of the diaphragms from 30 infected pigs and reported the incidence of larvae to be the greatest in the Crus muscle and then in descending order, the Dorsal Pars costalis, the Pars sternalis, the Ventral Pars costalis, and the Lumbocostal arch. The use of a 1 g sample from each carcass, as recommended by the EU, may also be subject to question because it may detect only 63.2% of the carcasses with a larval density of 1 per g of muscle (Figure 17-6). Similarly, the trichinoscope, which utilizes 14 pea-sized samples of the diaphragm crushed between two pieces of glass and evaluated microscopically, may lack precision because of worker fatigue and other technical problems. More rapid and accurate procedures need to be developed for the detection of the parasite at time of slaughter. An enzyme-linked immunosorbent assay (ELISA) for the detection of antibodies to *T. spiralis* has been developed but there is a 4- to 5-week period between initial infection in the pig and the presence of detectable antibodies in the animal's blood.[69]

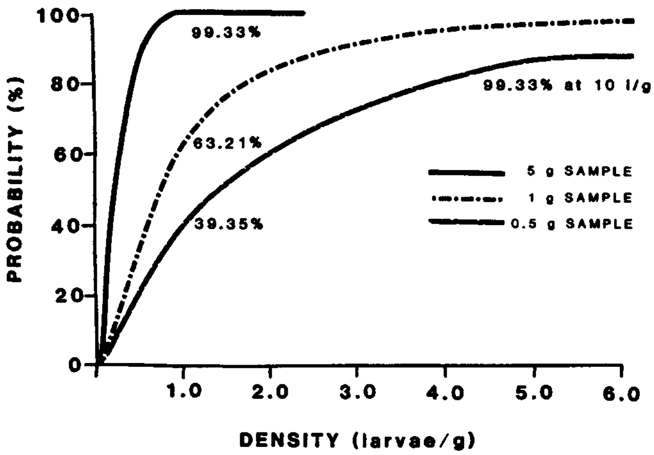

Figure 17-6 Influence of Sample Size and Trichinae Density on Probability of Detecting the Larvae. *Source:* Reprinted with permission from A.W. Kotula et al., Distribution of *Trichinella Spiralis* in the Diaphragm of Experimentally Infected Swine, *Journal of Food Protection*, Vol. 51, pp. 691–695, © 1988, International Association of Milk, Food and Environmental Sanitarians, Inc.

The typical distribution of *T. spiralis* larvae in pig muscles is shown in Table 17-12.[68] The resultant meat from such infected muscles can cause human illness unless the larvae are killed before the meat is consumed. In addition to pork, horse meat has also been implicated as a source of trichinosis in humans.

The state legislature of Illinois passed a law allowing the state Department of Agriculture to inspect

pig/swine herds serologically and to seize and destroy infected pigs.[109] An indemnity program compensated the farmer for the loss of the pigs. At present, enabling federal legislation is needed in the US to identify and seize, at the production level, any slaughter animals that have the parasite. Whereas serological testing of the herd at the production unit would be invaluable for identifying farms whose management practices allow cross-contamination of the pigs, testing of every carcass in properly pooled samples at time of slaughter is essential to overcome the potential inaccuracies of the serological tests. Inaccuracies are to be anticipated if (1) the severity of the infection is not adequate to elicit a definitive serological response or (2) the infection is adequate but recent so that the serology does not yet detect the infection.

Toxoplasma gondii

Human infection with *T. gondii* may result from the consumption of meat containing tissue cysts. Slaughter animals, including swine, sheep, goats, and poultry, may be intermediate hosts for *T. gondii*. The organism has not been isolated from beef raised in the US, and even experimentally infected cattle shed the organism from their tissues.[33]

Toxoplasma gondii has been found in pigs in every country where tests have been done. In the US, about 30% of pigs were seropositive for the organism, and of these, about 85% would be expected to have viable cysts in their tissues.[31] In the US, *T. gondii* seropositivity in sheep was 21% to 37%,[32,106] and 15% in horses.[106]

Cats and other Felidae, are the only known hosts for the parasite. Oocysts passed in the feces of infected cats may contaminate feed, water, or soil and thus can be ingested by slaughter animals.[33] The oocysts have been shown to persist in soil for 18 months, even in cold or dry weather.

Meat from infected animals, if not properly cooked, can cause infection in humans. In the US, up to 50% of the population is seropositive for *T. gondii*, whereas in continental Europe and South America, the rate is up to 90%.[34]

Leighty[80] recommended education, treatment of meat, and vaccination of cats as the most logical approaches for the prevention of human toxoplasmosis. Recommended treatments to destroy *T. gondii* in meat include freezing or cooking. Elimination of cats, domestic and feral, from animal production units is one of the simplest methods for the control of *T. gondii* in slaughter animals.

17.5 EFFECT OF STORAGE AND PACKAGING ON THE MICROFLORA OF RAW MEATS

17.5.1 Conditions Used

The spoilage of fresh red meats can result from microbial growth, enzymatic degradation, oxidative changes, and physical deterioration. Larger cuts can be vacuum packaged using oxygen-impermeable plastics. The storage life of chilled pork at 0°C, packaged in different atmospheres was 1.5 weeks in air, 3.0 weeks in high-oxygen modified atmosphere packaging (MAP) (30% CO_2 and up to 70% O_2), 5.0 weeks in low-oxygen MAP (up to 5% O_2), 5.0 weeks in vacuum, and 12 weeks in 100% carbon dioxide.[57] Low O_2 concentrations contribute to the rapid irreversible browning of red meat and therefore are not recommended for palatability reasons.[46]

Fresh red meats for retail sale are typically packaged on a moisture-impermeable tray with a moisture-absorbent pad under the meat, and an oxygen-permeable transparent plastic sheet overlay. Any excess moisture is absorbed by the pad, while oxygen permeability maintains the bright cherry red color due to oxymyoglobin.

The keys to maximizing storage life are to keep the meat only slightly above the freezing temperature, keep it clean, remove essentially all of the oxygen from the package, prevent oxygen from re-entering the package, and provide at least 25% carbon dioxide within the package.[57] Boneless pork primals, packaged in a 100% CO_2-controlled atmosphere, with stringent hygiene and temperature control were transported from the US to Japan; storage temperature was –1°C for unwrapped product and –1.5°C for cartoned product. This pork had a total storage life of 12 to 14 weeks.[57] In contrast, the previous practice of transporting this product gave an average total storage life of 6 weeks.

17.5.2 Spoilage Bacteria

Meat frozen to –40°C is considered to have all of its water in the solid state. At temperatures between –40°C and –2.2°C, variable amounts of water are frozen, depending on the meat composition. At temperatures above –2.2°C, the meat is unfrozen. Frozen meat generally inhibits bacterial growth but does not eliminate it entirely. To extend the storage life of chilled meat, it should be maintained as close to freezing as possible. During storage at –1.7°C for 18 days, the numbers of aerobic bacteria in ground beef increased by about 1 Log_{10} (Figure 17-7).[39] Table 17-13[91] indicates a 4 Log_{10} increase in the total aerobic count and the count of lactic acid bacteria on vacuum packaged beef stored 5 weeks at 2°C compared to 2.7 Log_{10} and 0.2 Log_{10} increase, respectively, at –1°C; after 10 weeks of storage, the difference was less. If one were to consider that –1°C provides 100% of the attainable storage life for chilled pork, then 0°C would be expected to provide 70%, 2°C would provide 50%, and 5°C would provide 30% of the attainable storage life.[57]

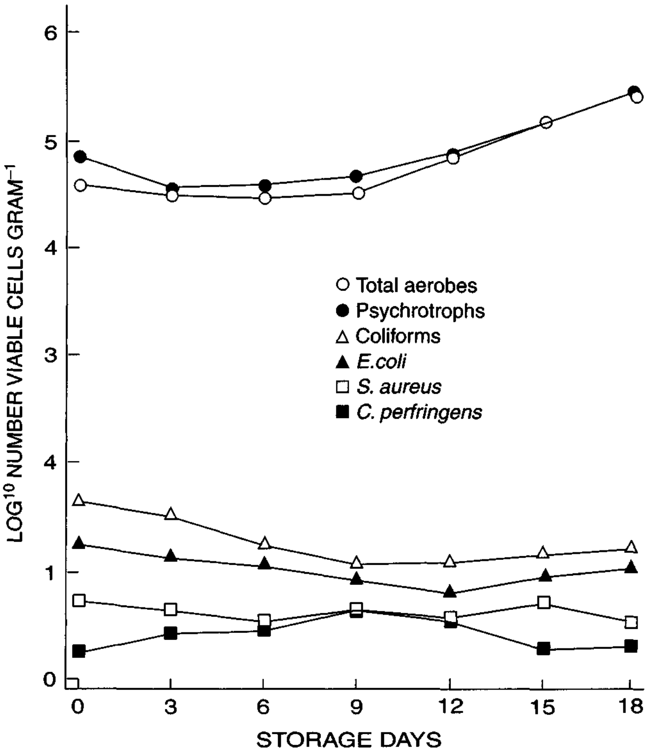

Figure 17-7 Effects of Storage at –1.7 ± 0.6°C for 18 Days on the Microbiological Quality of Ground Beef. Values for storage day 0 are mean Log_{10} counts of 16 samples; all other values are mean Log_{10} counts of 24 samples. *Source:* Reprinted with permission from B.S. Emswiler, C.J. Pierson, and A.W. Kotula, Bacteriological Quality and Shelf Life of Ground Beef, *Applied Environmental Microbiology,* Vol. 31, pp. 826–830, © 1976, American Society for Microbiology.

Vacuum packaging allows carbon dioxide to accumulate; the CO_2 inhibits pseudomonads and allows lactic acid bacteria to become predominant, thus extending the storage life of meat compared with that in air.[22] In such packages, the levels of CO_2 may exceed 20% v/v, whereas the O_2 is depleted to 1% or less. Table 17-13[91] shows the inhibitory effect of CO_2 on *Pseudomonas* spp., *Brochothrix thermosphacta,* and coliforms.

Temperature as well as atmosphere can affect the microbial flora of meat. The flora of fresh pork packaged with 40% CO_2 and 60% N_2 comprised mainly aeromonads, Enterobacteriaceae, and lactic acid bacteria when the meat was stored at 4.4°C, whereas at –1°C the most prevalent bacteria were aeromonads, *B. thermosphacta,* and lactics.[83] At 10°C, Enterobacteriaceae predominate on pork loins in packaging films with oxygen transmission rates of 1 to 26.5 ml $m^{-2}/24$ hours (OTR measured at 23°C, 0% relative humidity, 1 atmosphere pressure).[82] Other researchers found that lactic acid bacteria were the only bacteria found for the first 24 weeks of storage of pork loins at –1.5°C in 100% CO_2. When the loins were exposed to air and put on retail display at 8°C, the pseudomonads proliferated. *Brochothrix thermosphacta* and enterics grew sparingly under these retail conditions.[54] In another study, storage of pork loins in 100% CO_2 at 0°C resulted in a shelf life of about 3 months, and these conditions inhibited the growth of *B. thermosphacta,* Enterobacteriaceae, yeasts, and molds.[8] Vacuum packaging has been found to be generally as effective as any of the other modified atmospheres in extending the storage life.[91]

17.5.3 Potential Human Pathogenic Microorganisms

Chilling meat to temperatures close to –2.2°C inhibits the growth of foodborne pathogens. At 25°C, the typical generation time for psychrotropic bacteria is about 30 minutes; for 20°C, 75 minutes; for

15°C, 120 minutes; for 10°C, 200 minutes; and for 5°C it is 1,200 minutes.[104] Scott and Moberg[104] described the minimum growth temperatures of some of the more common pathogens as: *Y. enterocolitica*, –2°C; *L. monocytogenes*, 1°C; enterotoxigenic *E. coli*, 3°C; *A. hydrophila*, 0–5°C; nonproteolytic *C. botulinum*, 3.3°C; *Salmonella*, 7° to 10°C; *B. cereus*, 6° to 10°C; *S. aureus*, 7° to 10°C; proteolytic *C. botulinum*, 10°C; and *C. perfringens*, 12°C.

Although psychrotropic pathogens grow less vigorously at colder temperatures, bacteria cannot be expected to be destroyed by chilling or even freezing. *E. coli* O157:H7 survived 9 months storage at –20°C.[90] *C. jejuni* in ground beef was sensitive to freezing; the number of organisms inoculated into ground beef declined from 6 to 3 Log_{10} after 3 days storage at –15°C, but then remained fairly constant.[110] However, even very low numbers of potentially pathogenic bacteria may have a profound impact on the public health. As few as 500 cfu of *C. jejuni*[102] and fewer than 15 cfu g^{-1} of *E. coli* O157:H7 may cause illness.[30]

17.5.4 Parasites

Parasites, such as *Trichinella spiralis* and *Toxoplasma gondii*, can be killed by freezing. The USDA Certification Program prescribes temperatures and times of frozen storage that should be used to kill *T. spiralis* in pork.[14] These treatments are sufficient to reduce the number of viable encysted larvae of *T. spiralis* by approximately 99% (Table 17-6).[73] The cysts of *Toxoplasma gondii* are inactivated by freezing more readily than encysted *T. spiralis* larvae.[74]

17.6 EFFECT OF COOKING

17.6.1 Spoilage Bacteria

Bacterial contamination of steaks, chops, and roasts occurs mainly on the surface of the meat. During broiling, roasting, or frying, the heat of cooking destroys most vegetative bacteria. For ground beef patties and restructured steaks, however, the possible survival of bacteria in the center of the patty must be considered. Buck et al.[9] reported that raw patties with a calculated thickness of 1.7 cm should be cooked for 6 minutes on each side on a grill at 137°C to reduce total aerobic bacteria from 10^5–10^8 g^{-1} to about 10^2 g^{-1}; reductions were similar for lactose fermenters and *Escherichia coli*.

Coliforms were reduced to less than 1 Log_{10} from initial counts of up to 5 Log_{10}, by cooking 85 g wt beef patties, 9.2 cm in diameter and 1.3 cm thick, on a griddle at 149°C for 2.5 minutes per side or 177°C for 2 minutes or 204°C for 1.5 minutes.[64] The shortest cooking procedure, 1 minute per side at 149°C, reduced numbers of aerobic bacteria by a factor of 10, whereas in patties cooked at 149°C for 4 minutes (well done), 177°C for 3.5 minutes, 204°C for 3 minutes or more, or at 232°C for 2.5 minutes or more, the numbers were reduced by a factor of 10^4 (Figure 17-8).[64] Psychrotropic bacteria were more sensitive to heat than mesophilic bacteria.

17.6.2 Potentially Pathogenic Microorganisms

The US National Advisory Committee on the Microbiological Specifications for Foods recommended 60°C for 8.34 minutes, 62.2°C for 2.11 minutes, 65.6°C for 0.53 minute, or 68.3°C for 0.13 minute for the inactivation of *E. coli* O157:H7 in ground beef.[90] To ensure that consumers will not become ill from the consumption of meat containing potential pathogenic bacteria like *E. coli* O157:H7 or *Salmonella* spp. the FSIS recommends that meat be cooked thoroughly, that is, to 71.2°C (160°F).[45,114] Previously, they suggested meat be cooked until the pink color is no longer present but now they recognize that fat content and other factors can interfere with the use of color as an indicator of degree of doneness. Table 17-14 summarizes the FSIS current recommended cooking endpoint temperatures.[120,130] Ground meat must be cooked more thoroughly than intact muscle because of the occurrence of microorganisms in the center of ground meat patties, whereas the internal portion of steaks and roasts are considered free of bacteria. The minimum cooking endpoint temperature (65°C) is lower for pork cooked to medium doneness in USDA inspected establishments than for pork cooked by consumers (71.2°C) because commercial establishments use standardized cooking procedures.

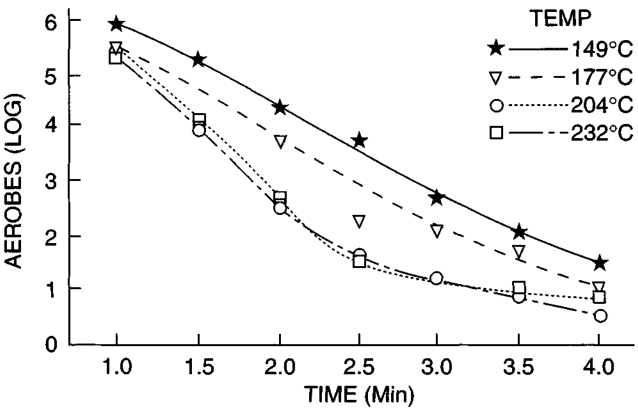

Figure 17-8 Mean Aerobic Bacteria per Gram of Beef Patty, 1.3 cm Thick, After Cooking at Various Temperatures and Times. *Source:* Reprinted with permission from A.W. Kotula et al., Destruction of Bacteria in Beef Patties by Cooking, *Journal of Animal Science*, Vol. 45, pp. 54–58, © 1977, American Society of Animal Science.

17.6.3 Parasites

Initial studies indicated that heating to 55°C was sufficient to destroy the larvae of *Trichinella spiralis*.[94,97] These studies predate some modern cooking methods such as the convection oven, deep fat frying, and microwave ovens. Some of these methods do not allow adequate warmup time to ensure destruction of trichinae at 55° or 58.3°C. Cooking infected pork chops to an endpoint temperature of 66° or 71°C by conventional oven at 162°C, or convection oven at 162°C, or flat grill at 204°C resulted in no detectable viable trichinae.[67] When the chops were cooked to the endpoints of 66° or 71°C by charbroiling or deep fat frying at 162°C, infective larvae were detected. Cooking by microwave is not reliable for the destruction of trichinae as there may be cold spots.[66] The Code of Federal Regulations[14] of the US provides minimum internal temperature and holding times necessary for the inactivation of *T. spiralis* larvae. *T. gondii* larvae are inactivated more readily by heat than *T. spiralis* larvae.

17.7 CONCLUDING REMARKS

At the production unit, animal health and welfare are not only essential for the production of wholesome meat, but are the basis on which sound eco-

Table 17-14 Minimum Internal Cooking Temperatures °C (°F) of Fresh Red Meats[120,130]

Well done			77 (170)
Leftovers			74 (165)

nomic decisions should be made. One cannot benefit financially from mistreated or sick animals. Producers of clean, healthy animals should receive a premium price, and those producing contaminated or feeble animals should receive a much lower price. Therefore, animals should be identifiable as to their source. We have discussed the influence of stress during shipping and holding on the predisposition of animals to shed potentially pathogenic bacteria. Standards should be established for the proper handling of livestock during transport and holding prior to slaughter. Financial penalties should be assessed when such standards are not met.

One of the worst enhancers of bacterial growth is extended or poor storage. At the slaughter facility, carcasses and their resultant parts should be systematically shipped out of the facility. Ingredient meats and fabricated cuts should be coded by batch and date so that meats are utilized sequentially, and that problem batches can be easily recalled if necessary. Fresh, unfrozen meat should not be stored "waiting for a better price" or to make a larger load. Shipping distances should be realistic to ensure that the meat arrives in good condition and with adequate shelf life for proper marketing. Trucks and loading docks should be refrigerated and temperature-sensing instruments and abuse disks should be utilized to detect breakdowns in the transport procedures. If fresh meat is being held in the cooler of a meat establishment, a warehouse, a distribution center, or the back room of the meat market, one may logically ask whether it is time that greater attention be given to the shortcomings of the marketing plan rather than attempting to extend the shelf life yet another day or two.

Minimizing the time of holding meat must be used in conjunction with maximal cleanliness and hygiene, and minimal temperatures during all stages of processing, fabrication, and any warehousing.

Regardless of the care taken by the meat industry, some fresh meat will reach the consumer, hotel, restaurant, or institution containing pathogenic bacteria. Therefore, cooking must be relied upon to provide the ultimate safety of the meat. Roasts that have only surface bacteria might be safe to eat less well done than ground beef in which the bacteria must be considered to be present throughout the meat. Methods are needed to be able to measure the internal temperature of hamburgers as they are being cooked on the grill.

Precooked meat is gaining greater acceptance. Current research appears to have solved the greatest deterrent to precooking, namely "warmed-over flavor." Proper cooking of prepackaged meats can provide pasteurized meat of various degrees of doneness that need only to be heated to be ready for consumption. Precooked roast beef is already available in many deli markets and is being used in some restaurants.

Consumer education is a continuing process that can greatly improve the microbiological safety of fresh meats. Every individual must become aware that fresh red meat must be kept clean and cold, and then it must be cooked properly.

18 Processed Meat Products

Martyn H. Brown

CHAPTER CONTENTS

18.1 Introduction
18.2 Factors affecting the microbiology of meat products
  18.2.1 Microorganisms of public health significance
  18.2.2 Microorganisms of spoilage significance
18.3 Production of meat products
  18.3.1 Raw materials control
  18.3.2 Process control
18.4 Product types
  18.4.1 Uncooked, processed meat products
  18.4.2 Cooked, uncured meat and meat products
  18.4.3 Raw-cured products
  18.4.4 Cooked, cured products
  18.4.5 Commercially sterile meat products
  18.4.6 Low and intermediate a_w products
18.5 Concluding remarks
  18.5.1 Manufacture and product use
  18.5.2 The use of HACCP and predictive models
  18.5.3 Emerging pathogen concerns
  18.5.4 Microbial destruction techniques
  18.5.5 Stabilization methods
  18.5.6 Selection/handling of raw materials

18.1 INTRODUCTION

Processed red meat products no longer have the appearance or perishability of fresh products because their formulation and treatment provides a range of preservation systems. They may be separated into a number of types according to intended storage temperature, ie, ambient, chilled (between 0° and 10°C), or frozen. The different preparation and preservation factors used to give equivalent microbiological stability are determined by the product type and customer usage. Their stability and safety relies on the interaction of their microflora with the nutrients and preservation factors, which can include processing and storage temperatures, water activity (a_w), pH, chemical agents, and packaging. Processing and formulation will kill a fraction of the initial microflora, inhibit or inactivate another part, and allow growth of the remainder.[73] The metabolic activity of the growing fraction can cause spoilage and can limit shelf life, while growth or survival of pathogens may cause safety problems.[227] Because chemical and physical factors alter the appearance, taste, and texture of the product, their use has to be a compromise between the safety and spoilage risk and product acceptability.

Meat and poultry products account for 5% to 10% of consumer spending on food in Europe and the United States (US). They are important vehicles of foodborne illness, particularly salmonellosis, and the economic cost of infections is very high (eg, in England and Wales (1988) the total costs were estimated between £231 and 331 million, of which over 60% was meatborne).[213] The majority of illness originates from raw meat (principally poultry) rather than from processed meat products. In 1996, the US Department of Agriculture (USDA) estimated that contamination of meat and poultry products with salmonella, *Escherichia coli*, campylobacter, and *Listeria monocytogenes* resulted in as many as 4,500 deaths and 5 million cases of illness annually. Associated medical and productivity costs (1993) were estimated at between 4.5 and 7.5 billion US dollars.

Safe, stable product designs can only be achieved within accepted sensory boundaries by identifying the target microorganisms and predicting their fate during processing, storage, and use. An integral part of product and process design is specifying the maximum input of microorganisms that must be inhibited or destroyed. Only when this has been done, can requirements for control, manufacturing and equipment,[7] quality assurance, and storage be defined. This is usually done using a hazard analysis critical control point (HACCP) study.[27,223] Modern techniques, such as time/temperature integrators and mathematical modeling,[148] have been used to assess or predict the impact on product safety and quality of formulation, process, and product handling-linked factors or changes, such as storage conditions or temperature abuse.[124] Combination preservation systems with many components or *hurdles* (Chapter 14) are widely used to minimize the sensory impact of single factors, such as salt or acid. If they were used individually, they would give products with an unacceptable taste.[94,130,132,133]

Despite continuous pressure for milder preservation and extended shelf life, processed meat products have a good microbiological safety record. However, since the 1980s a number of new pathogens such as *Listeria monocytogenes*[67,111,228] and the verocytotoxigenic types of *E. coli* have been associated with meat products.[52] To take account of their higher resistance to some factors, such as cold or acid,[137] product and process designs and manufacturing procedures have been altered to maintain safety standards. The food poisoning problems associated with *L. monocytogenes* contamination in the late 1980s and early 1990s led to a critical worldwide review by the industry of the cumulative impact on product safety of changes in product formulation, processing, and process hygiene. It was concluded that the use of chilled manufacturing facilities provided cooler conditions favoring *L. monocytogenes* rather than lactic acid bacteria or cold-tolerant Enterobacteriaceae that were previously found. Hygiene procedures had not taken account of this, and mildly preserved products containing low levels of a competing flora allowed the growth of *Listeria* species in chill-stored products. The public health impact of *E. coli* O157:H7 outbreaks in the US, Japan, and Scotland during 1996–97 will certainly continue this process of review, especially focusing on hygiene. During the 1990s the industry has increasingly used modern techniques to control the microbiology of products, namely:

1. systematic establishment of realistic microbial heat-resistance values for microorganisms in products
2. HACCP studies to identify "critical control points" in processes
3. targeting of cleaning and disinfection techniques at target microorganisms
4. using mathematical modeling to predict growth and survival
5. analysis and interpretation of the ecological pressures in products and factories to identify conditions selecting for hazardous microorganisms.

Use of these techniques should lead to a reduction in microbiological risks to both producers and consumers.

Where product safety relies on the customer to any significant extent, eg, chilled storage, restricted open shelf life, or thorough cooking, the main safety barrier provided by the manufacturer (apart from ensuring the absence of pathogens in the processed product) is effective labeling, aimed at specifying safe temperatures and restricting the open storage time. Although temperature control during manufacturing and distribution has improved (product temperatures of 5°C or less are not uncommon), it is doubtful whether there have been similar improvements in the domestic part of the products' life cycle. Home use, which includes the open shelf life, has become microbiologically the most risky stage, because the safety of meat products with milder intrinsic preservation systems relies very heavily on effective chill storage. Processing and formulation plus consumer use instructions must be designed to eliminate or control realistic microbiological hazards so that products are free from concern levels of pathogens and toxins and unspoiled at the point of consumption.

This chapter considers the microbiology of nonfermented red meat products (for information on fermented meats see Chapter 19 and for poultry-based products see Chapter 20).

18.2 FACTORS AFFECTING THE MICROBIOLOGY OF MEAT PRODUCTS

The rate of growth and survival of all microorganisms will be determined by the interplay of various factors[161] that are contributed by the product formulation, its processing (ie, procedures that substantially alter the numbers and types of microorganisms present or the environment in the food), packaging, and storage. They can be used by microbiologists to advise the product developer how to kill or inactivate pathogens or control the growth and activity of spoilage microorganisms. These can be classified as follows:

1. ***Intrinsic*** (Properties of meat products). These include the availability of nutrients (eg, extent of cell disruption, residual level of, or addition

of carbohydrates), pH (generally 4.3–7.0), a_w (<0.6–0.99), and the type of humectant (eg, salt, sugar, or glycerol), the presence and concentration of preservatives (eg, nitrite, sulfite, sorbate, benzoate, or parabens) or ingredients with antimicrobial properties, such as spices and smoke constituents. The use and permitted concentration of the latter two groups of substances is governed by law in most countries.[17,115] Interaction of intrinsic factors with temperatures outside the growth range can injure vegetative cells or spores and reduce their viability, as in salt and nitrite in the manufacture of luncheon meat, or enhance the production of inhibitory compounds as by the starter cultures in fermented products. The physical state, structure, and processing of the product will determine the type and distribution of growth. Surface colonies or slime will be found on whole muscle pieces; colonies will be distributed within comminuted or minced products and suspended cells found in liquid suspensions (eg, meat stocks, etc).

2. ***Extrinsic*** (Properties of the environment surrounding the foodstuff). These include process and storage conditions (frozen or sterilization temperatures), gaseous environment, eg, vacuum packaging with high CO_2 and low O_2 concentrations, and relative humidity.
3. ***Implicit*** (The interactions of the microbes—typically interactions with the lactic acid bacteria, associated with fermented products). This can lead to the suppression of some groups or species, by antagonism or competition for nutrients[177,195] or by chemical modification of the environment (eg, acidification or oxygen depletion).

18.2.1 Microorganisms of Public Health Significance

Processed meat products may contain a range of the microorganisms that can cause infection or intoxication of humans. They usually originate from the animal,[203] either forming part of its normal flora or being picked up from the environments it has passed through.[162] The skill of the slaughterhouse workers is an important means of preventing the contamination of muscle with gut contents and fecal matter, which may contain high numbers of infectious and toxigenic pathogens. The input level of microorganisms to products can be minimized by good layout, hygienic operational practices, and rapid chilling, but may be increased by poor hygiene (resulting in contamination) and badly controlled storage conditions (resulting in the growth of contaminants). If carcasses are cooled too slowly, stand for long periods (days), and microbiological contamination of deep muscle or bone has occurred, there is a risk of the growth of mesophilic bacteria, especially salmonella, clostridia, and bacilli, leading to spoilage or infrequently toxigenisis.[107,140] To cause harm, toxigenic pathogens need to grow sufficiently (*ca.* 10^6 g^{-1} or 10^8 cm^{-2} on the surface) for elaboration of toxin to be possible.[109] If there is insufficient cooling and prolonged storage, salmonella or clostridia may grow. Some infectious pathogens are hazardous at such low levels (eg, enteric pathogens such as *E. coli* O157 with a minimum infectious dose [MID] of *ca.* 10 organisms) that their survival is sufficient to be hazardous. *Listeria monocytogenes,* with a MID of *ca.* 100 g^{-1} and a low minimum growth temperature 0° to 2°C, may grow to high numbers in manufacturing areas and products held under chilled conditions,[25] thereby representing a hazard.

Many of the requirements of legislation and handling practices in slaughterhouses and refrigerated stores are designed to maximize the commercial quality and shelf life of meat for direct retail sale. Meat used in the manufacture of meat products requires a higher microbiological quality if processing technologies, such as drying with mild heat (or fermentation) are used as these have a limited ability to reduce levels of pathogens in the product. This requirement is most important in products intended to be eaten without cooking (for example, dry-cured hams, salamis, and raw meat spreads, such as Teewursts).

During manufacture and storage, a factory can introduce contaminants selected by its materials, processes, layout, hygiene (cleaning and disinfection systems), and operating procedures, especially times and temperatures.[15,58] The presence of indicator organisms, such as Enterobacteriaceae, may be used to provide information on the effectiveness of hygiene measures and heat processes. However, it is important that the correct analytical methodology be used to recover injured cells, and that the effectiveness of processing is not overestimated.[19,24] Rapid methods are being developed for the detection of pathogens in meat.[16,172]

Where products contain viable microorganisms, storage temperature and usage after manufacture will play a key role in determining their numbers at consumption. If products are not contained in a primary packaging able to prevent recontamination (for example, in multiportion packs), then storage hygiene plays an important additional role in determining safety and keepability.[86,142,143,222,234]

Infectious Pathogens

The most important infectious pathogens associated with red meat products are salmonellas,[112,178] verocytotoxigenic *E. coli* (VTEC),[34] and *Yersinia enterocolitica*. The Gram-positive, psychrotrophic pathogen *L. monocytogenes* is also an important pathogen.[85]

Salmonella is frequently associated with poultry and pork (detectable on 12% to >50% of carcasses) and less frequently associated with beef raw materials (2% to 5%). It has a low, but variable, infectious dose. Where the fattiness of the product protects the organism from gastric acids, this may be as low as 1 g^{-1} of product consumed. It is facultatively anaerobic and not inhibited directly by vacuum packaging. In meat products its minimum growth temperature is *ca.* 8° to 12°C, with a very extended lag phase; slow growth rates and increased sensitivity to intrinsic preservation factors occur at temperatures below 10° to 15°C. It can grow in mildly acidified meat products, such as hams, pates, and pies (pH 5.0–6.0) and survive at pH 4.4 (lactic acid) and in dried foods (such as cooked meat powder or flakes) for long periods. Survival under adverse conditions is often better at chilled (<10°C) than at higher temperatures, and hence chilling offers little protection against survival of infectious pathogens. It is inhibited by low a_w (<0.96) or *ca.* 8% s/w with 160 ppm nitrite (input level) at pH 6. The extent of survival or killing is dependent on drying conditions, pH,[138] and presence of organic acids, especially lactic acid.[12] As the mechanism of killing is by metabolic exhaustion, it can be killed by a combination of rapid acidification (pH <5.3 within 3 days), the reduction of a_w (≤0.94: >*ca.* 12% s/w), and storage for long periods (>21 days for a 4 log reduction) at temperatures above 15°C, as in the production of salamis. The cells are not heat resistant and are rapidly destroyed at the temperatures used for the cooking of meat products (typical D-value 0.04 minutes at 65°C). Heat resistance can be substantially greater at low (<0.94) a_w[178] and for some types, eg, *Salmonella senftenburg* ($D_{65°C}$ = >1.5 minutes). For further information on salmonella see Chapter 45.

Verocytotoxigenic *E. coli*, in particular *E. coli* O157:H7, are a major concern.[215] They may well be present in raw meats, (such as beef and lamb); the incidence in cattle in Western Europe and the US is very variable, eg, 0.9% to 8.2% of cattle in the United Kingdom (UK) surveys,[125] and is generally increasing for reasons that are not understood, but agricultural practices and better detection methods probably play a role. All are relatively heat sensitive (D_{60} = 0.37–0.55 minutes, z = 7.5°C), therefore reductions in excess of 6 logs are normally caused by cooking (ie, heating to temperatures usually in the range 65° to 70°C). Product composition, especially high fat level (>20% to 30%), reduces the lethality of heating.[1] Their presence in heat-processed meat products indicates inadequate processing (because of incorrect process design or operation/control) or post-process contamination.

There is conflicting evidence of their heat, salt, and acid resistance compared to other *E. coli*. Over the temperature range 10° to 35°C, they have been found to be more tolerant of salt, acid, and nitrite than salmonella, which is the traditional target microorganism. Resistance has been linked to an rpoS regulated protein, whose presence promotes survival (in foods) by offering protection against heat, salt, and acid challenges.[35] There is also some evidence that pre-exposure to stress, for example, an acidic environment, may increase resistance to that factor.[137] This feature has also been found in *Salmonella typhimurium*,[138] and enteropathogenic *E. coli.* For further information on *E. coli* see Chapter 43.

Yersinia enterocolitica is a member of the Enterobacteriaceae, of which some serotypes are pathogenic to humans. These have been isolated from chilled pork, beef, and poultry products, especially if they have an unusually high (>5.9) pH. They are heat sensitive and can remain viable for long periods in acid or low a_w products, high CO_2 (10% v/v) packs, or at chill temperatures (4°C). Therefore, it is important to ensure that not only growth but also survival is minimized by the formulation and processing/storage conditions used for ready-to-eat foods, especially prevention of cross-contamination. For further information on yersinias see Chapter 49.

Listeria monocytogenes is a common contaminant of meat and poultry.[111,151] Its minimum growth temperature is 0° to 2°C (typical lag periods 3 to 30 days and doubling time *ca.* 100 hours). This allows it to become established in cool, damp manufacturing environments, such as on meat processing equipment and in chill rooms.[234] It is able to survive for long periods (*ca.* 100 days) in the presence of high concentrations of salt (10% to 30% s/w) under chilled conditions. The increase in incidence of *L. monocytogenes*[151,228] has probably resulted from the cumulative effects of small changes in processing, which altered a particular ecological niche sufficiently to replace one type of microorganism, eg, lactic acid bacteria, with another closely related one, eg, *L. monocytogenes*. Prolonged chilled storage allows good growth in many meat products.[91] Many current quality assurance procedures are specifically intended to reduce its incidence in processed meat products.[21] They involve pinpointing likely sources of contamination, eg, places likely to support listeria growth, such as slicers, heat exchangers in chill rooms, and conveyor belts, and then using cleaning and disinfecting agents (such as amphoteric surface-active agents), which are effective against listeria.

The factors leading to its prevalence in meat processing areas also allow it to grow in mildly preserved meat products, eg, it grew at 4°C in a meat product with pH *ca.* 5.5 containing 125 ppm nitrite or 0.5% w/v phosphate.[29] It can compete with and may outgrow spoilage microorganisms, such as lactic acid bacteria with minimum growth temperatures *ca.* 8°C, eg, in pate stored at 8° to 10°C.[85,150] It can grow at pH 4.4–4.6 and in some high-salt products (10% sodium chloride on water), even at chill temperatures. Preservatives that have proved effective inhibitors include sodium lactate (4%), potassium sorbate (0.3%), and nisin (400 IU ml^{-1}).[29] Lactic acid bacteria may produce natural antimicrobial compounds that are active against it and other pathogens.[5] *Listeria monocytogenes* is not heat resistant (typical D_{70} = 8 to 16 seconds, z = 7.5°C); a current UK recommendation of heating to 70°C for 2 minutes (or an equivalent heat treatment) is sufficient to ensure its elimination from foods. There is some evidence that processing treatments involving sublethal stress can increase heat resistance.[69] Because only a small part of the population is sensitive to infection by *L. monocytogenes*, there is considerable debate on suitable limits for manufacturing specifications. For further information on *L. monocytogenes* see Chapter 44.

Toxigenic Pathogens

These microorganisms, with the exception of *Clostridium perfringens*, are hazardous because if they grow to high numbers (*ca.* 10^6 g^{-1}),they may produce toxins in meat products; *C. perfringens* produces its toxin in the gut. Toxins may be preformed by growth in raw materials and are not destroyed by freezing. Under certain conditions, toxigenic species may grow without toxin production, but processed foods in which it has grown to high numbers and then been destroyed may cause food poisoning because of the persistence of the toxins. For instance, staphylococcal enterotoxin is very resistant to heating (may survive at 120°C for 10 to 20 minutes), whereas the organism is heat sensitive (typical D_{60} = *ca.* 1 to 5 minutes).

Staphylococcus aureus grows from 6.5° to 50°C (reported range in meat products 10° to 37°C),[219] from pH 4.5–7 (minimum pH 5 in meat products) and above a_w 0.85 (>19% salt on water) in the absence of other preservation factors. It is a frequent contaminant of meat[203] and may produce 1 or more of 10 types of enterotoxin (SEA – H); strains producing SEA and SED are mainly responsible for human food poisoning. Toxin formation in raw meats has not been detected and it is thought that implicit factors, such as the competing flora, may prevent toxigenisis under otherwise favorable conditions.[156] Contamination by food handlers of mildly preserved processed products, where any competing flora has been eliminated by heating or is inhibited by low a_w, coupled with warm storage conditions is a major cause of staphylococcal food poisoning.[109] Under warm semidry conditions, it may become established on food processing equipment and produce toxin. For further information on *S. aureus* in meat products see Chapters 19, 20, and 47.

Clostridium botulinum Types A, B, and F have been associated with food poisoning caused by meat products.[93] The spores if present in meat are usually at a low frequency and number (*ca.* 1 kg^{-1}). Spores of both proteolytic and nonproteolytic strains of *C. botulinum* will survive pasteurization—Type A and proteolytic Type B (typical $D_{112.8}$ = 0.15 – 1.32 minutes, z = 8°–10°C); Type E (typical D_{80} = 0.33–4.3, z-value 8°–10°C). The nonproteolytic strains (Type E and nonproteolytic strains of Types B and F) can grow during prolonged storage at temperatures >5°C (minimum growth temperature 3.3°C), and at a minimum pH of 5.0, under otherwise optimum growth conditions. These strains present a greater food poisoning hazard than the proteolytic types, as their growth to levels forming hazardous concentrations of toxins may occur in the absence of spoilage. The proteolytic strains (Type A and some Types B and F) can grow over the range 12° to 50°C and down to pH 4.6, and to an a_w of 0.94/0.95 (with salt as the humectant). Psychrotrophic, nonproteolytic strains of *C. botulinum* Type E have only been associated with fish products,[93] but can grow very slowly in mildly heated, lightly preserved (*ca.* 3.5% s/w) meat products at commercial chill storage temperatures,[211] and are therefore a potential hazard. Preservatives such as nitrite and salt will reduce or prevent the growth of *C. botulinum* in a meat product, depending on the concentration present,[184,185,186] and an adverse redox potential (eg, the presence of oxygen throughout the product) and the presence of inhibitory microorganisms (such as lactic acid bacteria) may prevent its growth.[39] The toxin of *C. botulinum* is heat labile (inactivated by 85°C for 5 minutes), but heating should not be relied on as a means of ensuring the safety of products where the growth of *C. botulinum* is suspected. For example, botulism (from Type A toxin) has been caused by the consumption of stew that had been cooked and then stored at ambient temperature for 3 days and reheated. For further information on *C. botulinum* see Chapter 41.

Bacillus cereus is widely distributed in soil and vegetation and may be particularly present in meat products that are seasoned with spices or contain cereal or rice.[84] It only becomes a hazard when the cooking process has eliminated competitive species, but left viable spores of *Bacillus cereus* (typical D_{100} = 5 minutes, z = 10°C). Decreasing pH and increasing NaCl and sodium nitrite levels increases the lag phase and extends generation times.[13] For further information on *B. cereus* see Chapter 39.

Clostridium perfringens Type A is ubiquitous in meat products and characterized by a relatively high minimum growth temperature (*ca.* 12°C) and salt tolerance (6% s/w).[183] Because it can grow and sporulate rapidly in meat products at temperatures in the 26° to 51°C range, it is a hazard in cooked meat products that cool slowly because of large containers, or product-unit sizes, or the use of inefficient chills.[41] Growth of *Clostridium perfringens* has been observed in meat soup, sausages, and meatballs.[146,147] For further information on *C. perfringens* see Chapter 42.

18.2.2 Microorganisms of Spoilage Significance

Microbial spoilage of meat is mainly due to the aerobic or anaerobic growth of bacteria. The species involved include *obligate aerobes* (*Pseudomonas, Acinetobacter/Moraxella, Aeromonas, Alteromonas*); *facultative anaerobes* (*Alcaligenes*, Enterobacteriaceae and coliforms, *homo- and hetero-fermentative* lactic acid bacteria including *Leuconostoc, Pediococcus,* and the *Lactobacillus sake/curvatus* group[57,118] and streptobacteria); *Brochothrix thermosphacta*[90]; micrococcaceae, pediococci, enterococci,[49] and *Bacillus* species; and *obligate anaerobes,* such as clostridia. Yeasts and molds (*Geotrichum, Thamnidium,* and *Cladosporium*) may also cause spoilage.

Spoilage microorganisms are commercially significant in meat products when their numbers reach around 10^7 g^{-1}, resulting in sensory changes limiting acceptability and shelf life.[107] Metabolism during and after growth ceases causes changes to taste, odor (eg, sour or ammoniacal), or appearance (eg, gas production or color change—loss of the red color associated with meat or cured meat pigments and replacement with brown, gray, or green). In some extreme cases, the texture may also be altered, by the reduction of pH (caused by acid production) altering the water-holding capacity of the meat, the production of slime, and eventually the breakdown of structural proteins. Because processed meat products contain protein and fat, and in some cases cereal ingredients, the impact of each ingredient on the nature and activity of the spoilage flora is important in determining spoilage. The main changes are as follows: the formation of organic acids and other metabolites, including slime, from carbohydrate breakdown; lipolytic activity; breakdown of complex proteins, peptones, and polypeptides; and production of carbon dioxide and hydrogen peroxide.

Under chilled (4° to 10°C), aerobic storage conditions the surfaces of unpreserved meat products are usually spoiled by the aerobic, psychrotrophic "non-pigmented" pseudomonads, such as the *Pseudomonas-Alcaligenes-Acinetobacter-Moraxella* group, *Kurthia*, or the coryneforms.[217] Their main metabolic products are CO_2 from carbohydrate metabolism, but rapid surface growth can lead to localized carbohydrate depletion and a switch to the metabolism of nitrogenous compounds producing a pH rise and putrid spoilage from amine production. Even under these conditions, carbohydrate metabolism can continue below the surface, and at low oxygen tensions, causing a pH drop because of lactic acid production. If the surfaces dry out during storage (the minimum a_w for the growth of the aerobic psychrotrophs is *ca.* 0.95), growth of the lactic acid bacteria (especially lactobacilli or leuconostocs[57] or *B. thermosphacta*) can cause distinctive types of spoilage. It also occurs if the availability of O_2 is restricted and the level of CO_2 increased, as in a vacuum pack, or if the spoilage flora is distributed below the surface so that the supply of O_2 by diffusion is limited, as in comminuted products like burgers. In the absence of growth of lactic acid bacteria, which reduce the pH, *Bacillus* species including proteolytic types may grow after prolonged storage.[61] If anaerobic conditions develop at high pH (>5.6), then there is growth of the facultatively anaerobic Gram-negative bacteria and putrid spoilage results; they are suppressed when the pH is below 5.4–5.9. If the a_w is below 0.98, the Gram-negative bacteria are progressively replaced by the Gram-positive species, such as lactobacilli, enterococci, and streptococci,[49] *B. thermosphacta*, coryneforms, or *Kurthia zopfii*. Eventually, when the a_w drops below 0.93, bacterial spoilage becomes limited to the micrococci (which are salt-tolerant strict aerobes) and then yeasts and molds become the main spoilage agents.

Many preservation systems use selective factors to steer the type of spoilage or suppress the growth of particular microbial types that cause unpleasant changes.[130] For example, lactic acid bacteria cause the normally acceptable souring of ham and other lightly cured meat products. They are selected by salt level, nitrite, and vacuum packaging and slowly metabolize carbohydrates to acidic products. The drop in pH and accumulation of organic acids (mainly lactic acid, to levels *ca.* 0.5%) prevents putrid spoilage resulting from the ammoniacal products of microbial protein and peptide degradation. Many biochemical methods are available for determining spoilage of meat.[152] Some species of lactic acid bacteria may additionally produce bacteriocins, which are inhibitory to other species.[5]

18.3 PRODUCTION OF MEAT PRODUCTS

18.3.1 Raw Materials Control

Meat products require raw materials of good microbiological quality, but even so they may be contaminated with pathogenic microorganisms, such as salmonellas or *Staphylococcus aureus*.[203] This is especially important if processes have a limited ability to reduce microbial numbers. For example, salami processes typically cause a maximum of 4 log reductions in numbers of salmonella, and the heat processes used for luncheon meats only produce a stable product with an input level of bacterial spores of below 1,000 g^{-1}.[173] Hygiene precautions and the rate of refrigeration will affect the level of contamination and frozen storage can halt growth. There is little evidence that the activity of enzymes of animal origin causes deterioration in frozen meat products, even though they may be concentrated in the unfrozen water and have a long period, typically >1 year, for activity. Most deterioration is caused by chemical oxidation and desiccation. Growth of psychrotrophic and psychrophilic spoilage microorganisms may occur during cooling and chill storage depending on temperature; at below –6°C growth will be halted. Sometimes meat raw materials are stored vacuum packaged or under a modified atmosphere to slow growth and prolong shelf life. The initial pH of such meat and the O_2 permeability of the packaging film are critical to development of the spoilage flora and hence the type of spoilage found.[87] Below 10°C, meat with a pH in the normal range (5.5–5.8) will support the growth of lactic acid bacteria and eventually becomes sour. Meat with pH values >5.8, especially when packaged in films providing a poor O_2 barrier, supports the growth of *Alteromonas putrefaciens* and *Enterobacter liquefaciens*, which produce H_2S and cause greening of the meat.[163]

Some manufacturing technologies may involve lengthy periods of preprocessing before there is any process step that inhibits or reduces numbers of microorganisms. The breakdown of structure, by processing, may speed up growth of any contaminants. For example, ham manufacture may involve the tumbling or massaging of meat pieces at low operating temperatures, typically 4° to 20°C, for periods of hours (up to 48 hours) to improve their cohesion and water-binding during cooking. Depending on temperature during this period lactic acid bacteria may grow and reduce the pH, or reduce the oxygen tension to such a low level that curing cannot take place. During such processes, meat oxymyoglobins are not deoxygenated to give myoglobin (which forms a stable nitroso-pigment), but are reduced to metmyoglobin at the low pO_2, resulting from microbial consumption of oxygen. Metmyoglobin forms an unstable nitroso-pigment[128] and causes color defects in hams. Microbial production of hydrogen peroxide can oxidize meat pigments, also preventing the formation of a stable nitroso-pigment, and leading to color defects. Hence, the effects of prehandling and processing become critical if the growth of microorganisms exceeds a level that can be controlled by the formulation or subsequent processing conditions.

Other animal products including liver and offals, fat, blood, hide, and mechanically recovered meat (MRM) may be used as raw materials.[220] Because of their low commercial value, the bones yielding MRM may not have been rapidly chilled. This coupled with disruption of the structure of the tissue and mixing of contaminants during separation provides an opportunity for microbial growth and spoilage to occur before processing. This is in contrast to muscle where the interior is usually sterile, spoilage is confined to the outside, and is relatively slow. The breakdown of structure by processing may give a higher surface area-volume ratio in products such as MRM or liquids and speed up growth of any contaminants, promoting rapid spoilage. Hence, meat products may be more heavily contaminated with spoilage and pathogenic bacteria (eg, *Staphylococcus*

Next Page

aureus, clostridia, and Enterobacteriaceae) than chilled "intact" muscle. Because of higher temperatures caused by the high energy (pressure or abrasion) processing, equipment designed to remove flesh from the surfaces of bones, equipment hygiene and its maintenance, and the initial microbiological quality of the raw material, especially its temperature and storage period, needs to be carefully controlled. MRM is usually stored frozen until it is used. Downstream, manufacturing conditions should be designed to take account of the higher concentration of microorganisms it can introduce. Therefore, these materials should be considered less stable and their shelf lives should not be based on those achieved under similar conditions by conventionally butchered muscle tissue. Nonmuscle materials may exhibit typical forms of spoilage, for example, hemolytic spoilage may be associated with liver and kidneys and lipolytic spoilage with hides and fatty tissue.

18.3.2 Process Control

Pathogenic microorganisms and/or their toxins may be present in raw materials or introduced during processing, storage, or usage; realistic incidence and amounts should be identified using a risk assessment.[27] The means available for control should be based on the use of HACCP to identify the Critical Control Points in the process.[199] Predictive models for growth, survival, or killing of the major spoilage organisms and pathogens may be used for risk assessment. Its output and the HACCP study should be used to determine the design and the operational targets or limits for the manufacturing process. A HACCP study will only be effective if a manufacturing plant operates against a background of Good Manufacturing Practice (GMP) such as outlined in Codex,[37] in the European Union (EU) Regulations,[63] or the US Federal Register.[73] Topics typically covered by GMP guides for the meat industry include the following:

1. Minimum requirements for the manufacturing environment, especially layout to prevent cross- or recontamination of in-process material or product with pathogens or spoilage microorganisms
2. The hygienic design and construction of buildings, stores, and equipment
3. Process operation, control and monitoring
4. Lot traceability
5. Maintenance of buildings and equipment
6. Sanitation, hygiene, and pest control
7. Personnel, skills, and competencies

The Critical Control Points (CCPs) are those additional process activities or constraints on formulation, packaging, storage, or usage that must be applied to ensure safety (and keepability). These may include the following:

1. Control of temperature and time (eg, cooking, sterilization, cooling, and storage conditions)
2. Activities and conditions providing the intrinsic properties of the product relevant to the preservation system (eg, acidification, reduction of a_w, or addition of chemical preservatives such as nitrite or sulfite)
3. Packaging, seal integrity, and physical and gas barrier properties of the primary pack; correct labeling may be a CCP if the consumer is involved in the safety chain (ie, for cooking or use of controlled (frozen or chilled) storage conditions)
4. Product unit or batch physical dimensions
5. Storage conditions.

18.4 PRODUCT TYPES

18.4.1 Uncooked, Processed Meat Products

Typical products are fresh sausages and burgers, which may be stored frozen or chilled and are intended for cooking by the customer. British fresh sausages are made from finely chopped and mixed meat, fat, rind, herbs and spices, and a cereal (carbohydrate) component—rusk. They contain sodium metabisulfite as a preservative and are stuffed into edible casings made from collagen or sheep gut. Burgers are made from more coarsely chopped meat, usually they do not contain nonmeat ingredients. They contain salt to aid binding of the meat particles to one another and are molded into the typical patty shape using pressure. The general manufacturing process for fresh sausage and burgers is shown in Table 18-1.

The manufacturing processes do not cause any reduction, and may even increase, microbial numbers if processing conditions are too warm and hygiene is poor. Immediately after manufacture, these products will contain any spoilage (such as Gram-negative aerobic bacteria, lactic acid bacteria, and Enterobacteriaceae) and pathogenic microorganisms (such as salmonella, *L. monocytogenes*, verocytotoxigenic *E. coli*, *Campylobacter* spp., or *Y. enterocolitica*), derived from the meat raw materials. During storage, temperature and access of oxygen play a major role

Table 18-1 Manufacturing Process for Burgers and Sausages

Typical Process Step	*Microbiological Importance*
Selection and preblending of raw meat and fat materials	Concentration and types of microorganisms in raw materials
Mincing or flaking	
Mixing with ingredients, eg, rusk and sulfite (sausages) or onion (burgers)	Preservative effect of sulfite, nutrient effect of carbohydrate, time and temperature (typical total process duration usually <8 hours and <12°C)
Forming, eg, patty shape (burgers) or stuffing into casings (sausages)	
Storage, frozen (≤–12°C for up to 1 year) or chilled sausages (≤10°–15°C for 1–2 weeks)	
Burgers (<5°–10°C for 7–10 days)	

in determining spoilage and the survival or growth of pathogens.

During chilled storage of British fresh sausages, a facultatively anaerobic spoilage flora develops.[10] It is selected by the preservative sodium metabisulfite (450 ppm maximum input level, controlled by legislation) and some additional factors. These include the presence of carbohydrates from the rusk and the low subsurface oxygen tension resulting from surface growth of aerobes. The flora is numerically dominated by either *Brochothrix thermosphacta* or yeasts[44] growing beneath the surface—depending on the origin and previous storage conditions of the meat.[44,50] Meat from some manufacturers, typically those with very dry, warm chills, may develop a flora containing substantial numbers of lactic acid bacteria. At chilled storage temperatures, sulfite inhibits growth of Enterobacteriaceae[9] especially salmonellas, which are a frequent contaminant[11]; *Campylobacter* species are inhibited by storage conditions.[164] When natural casings are used they may contribute halo-tolerant and enteric bacteria to the storage flora.[180]

In contrast, the spoilage flora of chill-stored burgers, which do not contain preservatives, is similar to that of fresh, aerobically stored meat, unless they are vacuum packed. In both cases, their spoilage flora depends mainly on pH[43] and oxygen tension. During aerobic storage, spoilage is caused by the Gram-negative species, producing CO_2 as an initial end-product and then deamination metabolites. During their typical shelf life (about 7 to 10 days at 5° to 10°C), strict aerobes (such as pseudomonads and acinetobacters) form only a small part (<1%) of the spoilage flora, because microorganisms are distributed relatively uniformly throughout the product and mostly subject to a low pO_2. Cross-sectioning of the product can show the progressive depletion of oxygen beneath the surface by microbial metabolism, as evident from changes in meat pigment color from red to brown; oxidation at low pO_2 gives metmyoglobin, which has a typical brown color.

Temperature determines which microbial contaminants grow; at <12°C salmonellas are inhibited, but *L. monocytogenes* may grow down to 1° to 2°C and other microbes may survive (eg, *Campylobacter*). *Staphylococcus aureus* may produce toxin if low-count meat is stored above about 20°C.[62] For complete inhibition of spoilage species storage below the product freezing point, typically –2° to –6°C, is required.[21] Under deep freeze conditions some species (especially Gram-negative bacteria) may be injured by the freezing process. In practical terms, freeze injury cannot be used to improve the safety of the product, but it is a major influence on the microbiological methods that need to be used to estimate microbial numbers. For an accurate estimate, resuscitation techniques will need to be used.[65,74]

As these products contain raw meat, customer safety depends on cooking to provide an adequate reduction in numbers of infectious pathogens.[77] Product dimensions and cooking instructions should ensure that good quality and a safe product results from use of the recommended cooking conditions. Undercooking will allow the survival of any pathogens present. For example, inadequate deep fat frying caused a hospital outbreak of salmonella food poisoning.[64] Time/temperature requirements may be affected by the storage conditions (eg, temperature at the start of cooking) and product composition.[1] Freezing and fluctuating temperatures inducing stress responses or producing stationary phase cells can also increase microbial heat resistance (eg, *E. coli* O157:H7).[110] Various experimental methods, besides direct temperature measurement (which may be inaccurate if the slowest heating point in the product is not correctly identified), have been developed to determine the endpoint temperatures of products after heating, such as inactivation of lactate dehydrogenase.

Microbiologically Important Features of the Manufacturing and Formulation Technology

The key microbiological mechanisms at work in these products are selection and distribution of the microflora by processing, especially temperatures, cutting and mixing, and the packaging system. The controlled addition of a preservative, such as sodium metabisulfite, and the implicit factors, such as inhibition of Enterobacteriaceae by the growth of lactic acid bacteria and prevention of enterotoxin production by *S. aureus* by the growth of the spoilage flora, are also important. The mincing (or grinding) and mixing processes will disrupt the cellular structure of the meat, liberating cell contents, and dispersing microbial cells more uniformly within the meat matrix.[116] This may affect the apparent microbiological quality of the product as when the variability (standard deviation) of the log mean counts is reduced as a result of the mixing processes (standard deviations are typically reduced from $\pm 1.5 \log_{10}$ to $\pm 0.25 \log_{10}$), and the measured average (mean log) count will increase.[116] This increase may cause detectable numbers of any microorganisms present at low numbers to rise above the detection level of an analytical method, apparently indicating contamination during processing. This effect is exaggerated in mechanically recovered meat (MRM). The microbiological quality of these products will reflect directly the quality of raw materials, including any increase or recontamination during processing and storage. Product developers assigning product shelf lives should always take account of realistic starting levels of spoilage microorganisms, the microbial level at which unacceptable quality loss is caused, and the likely storage conditions, which will dictate microbial growth rate and hence the spoilage rate.

As cooking prior to the consumption of a raw meat product is an essential part of the processing safety chain, minimum cooking time and temperature must be ensured by providing the consumer with validated cooking instructions.[64] There is some debate over the necessary reduction in pathogen numbers that a cooking process should deliver,[170] but a 4 log reduction in infectious pathogens should be considered a minimum, with 6 logs as a target. The effectiveness of any cooking instructions should be validated, for example, by the use of the bio-integrator method.[97] Different types of cooking methods vary in their heating ability. For example, microwave heating does not produce an even or predictable distribution of heat and therefore temperature. Thus, it cannot be relied on to pasteurize products consistently.[181]

In-process controls focused on temperature and hygiene should be backed up by supplier auditing. Specifications should cover the control and monitoring of raw material quality, manufacturing hygiene, storage, and distribution temperatures.

18.4.2 Cooked, Uncured Meat and Meat Products

Typical products are heat-set joints (usually beef, pork, or poultry). A typical shelf life of a cook-in pack at 0° to 3°C is 12 months) but when sliced, a typical shelf life would be 2 to 3 weeks under normal retail chill conditions. As the meat components of ready-to-eat meals, pies, small goods, or savory products, containing offals such as liver or heart the typical shelf life would be 1 week. They may be oven or fryer cooked or produced using *sous vide* technology resulting in an extended storage.[160]

The main microbiological hazards arise from microorganisms surviving the manufacturing heat process or from recontamination after heating. Products may be frozen or stored under chill conditions. Under chill storage conditions, vacuum packaging may be used to inhibit the growth of aerobic species.[102] The type of packaging and packaging atmosphere modify the type of spoilage and may also reduce the risks of pathogen growth during chilled storage.[105] Typical cooking processes will kill vegetative cells, but will not reduce numbers of bacterial spores, which remain a hazard if storage temperatures fall within their growth range. The infectious and toxigenic vegetative pathogens—salmonella, *L. monocytogenes, S. aureus,* and *Y. enterocolitica*—generally do not survive commercial heat processes, unless there is underprocessing. Their presence usually results from recontamination after cooking.[103,104,106] Where marginal heat processes are used, for example, in *sous vide* products, heat-resistant vegetative microorganisms such as streptococci and lactobacilli may survive cooking and cause spoilage.[103] However, spoilage bacteria are far more commonly introduced during processing, especially if there is unhygienic handling of the unwrapped product during cooling, slicing, and packaging. Often contaminants will have been selected, or be well adapted to the environment in the factory and equipment, and hence able to grow in the product. Storage temperatures below about 8°C will inhibit lactic acid bacteria (LAB) but can allow the growth of *Listeria* spp. and psyschrotrophic Enterobacteriaceae, which are often inhibited by growth of LABs at higher temperatures. Lactic acid and lactates have been used to prevent growth at lower temperatures.[98,101] Unusual cold-growing clostridia causing spoilage have been isolated from vacuum packed products, such as cooked pork or beef.[126]

In the *sous vide* process, products are vacuum packaged before cooking to retain their shape and maximize heat transfer; they usually receive mild heat processes in the 65° to 75°C range. Because spores may survive these low heat processes, storage at a low temperature (below 4°C) or for a restricted time at a higher temperature (eg, up to 2 weeks at 10°C) is essential to prevent the growth of psychrotrophic bacteria, especially *C. botulinum*.

In some countries, chemical additives, such as organic acids and their salts, may be included in chill-stored products to slow the growth of pathogens (and spoilage bacteria). However, this approach has met with limited success because of the adverse impact on the taste of bland products. Lactic and citric acid, or sodium acetate (0.5% w/w to give concentrations of *undissociated* acid 0.01% to 0.05%), have been used.[207,232] Also sorbate (0.26%)[214] has been used to improve the stability of products such as low-salt turkey. Lactate (*ca.* 3% w/v) and salts of *para* hydroxy benzoic acid have been used to inhibit *S. typhimurium*, *E. coli*, and *L. monocytogenes* in pork products stored at temperatures between 5° and 20°C.[99,101,206,233] The product applicability and use concentration of these preservatives is limited by sensory acceptability (usually concentrations over 0.5% are organoleptically unacceptable), and permitted additives are specified by law in most countries.

Microbiologically Important Features of the Formulation, Manufacturing, and Packaging Technology

As the products are largely unpreserved, microbiological quality relies on control of temperature and prevention of recontamination; see Salvat et al.[192] for a HACCP study of a typical process for the production of a vacuum packed chill-stored product.

Products are cooked to give characteristic tastes, textures, and colors. From a microbiological point of view minimum coldest point temperatures in the range 65° to 85°C are sufficient to destroy (eg, 6 log reduction) vegetative spoilage and pathogenic bacteria.[66] Accurate measurements of the minimum or integrated heat processes are required because generally the lowest possible heat treatments are used to minimize texture changes and weight losses due to "cook-out" of soluble proteins. It is also important that temperature distributions in heating vessels are determined and product heating times take these into account. Use of indirect indicators of the application of defined heat treatment has been proposed, eg, the use of denaturation of acid phosphatase for determining the extent of heating given to picnic hams.[119] After cooking, high standards of process hygiene, including effective raw/cooked segregation are necessary to prevent cross- and recontamination of products with microorganisms from raw materials or the indigenous flora of the factory. In addition to forward flow, the clean room concept is often applied and includes hygiene control measures such as prohibition of entry and separation of personnel from factory areas handling uncooked material, specified clean clothing, a filtered air supply, and a cool dry environment with good cleaning and disinfection.[22,36,131,204] Where these processes and areas are well managed, packed meat may be so clean that spoilage bacteria are only infrequently detected; a spoilage flora of variable composition can originate from process survivors (eg, spore formers), the factory environment, and any process aids used.[231] A typical process for the manufacture of sliced roast beef is shown in Table 18-2 and for a cooked meat pie in Table 18-3.

Table 18-2 Typical Process for Sliced Roast Beef

Process Steps	*Microbiological Importance*
Selection and butchery of raw meat and fat materials	Concentration and types of microorganisms
Tumbling and massage of prime cuts, introduction of salt and phosphate	pH modification
Trimming	
Packing into clamps or nonedible casings for shaping	Dimensions of pack
Cooking process in steam, water, or air, typically 68°C chamber temperature; >65°C center temperature	Cooks product and eliminates spoilage and pathogenic vegetative bacteria; bacterial spores are unaffected
Cooling in container, <10°–15°C within 4 hours	Under "high hygiene conditions" to prevent recontamination
Unpacking	"High hygiene conditions" to prevent recontamination
Roasting, to provide surface browning—*ca.* 180° to 250°C	May provide surface decontamination
Air cooling, <5°C in <12 hours	
Slicing	Hygiene of slicer is mainly responsible for initial flora on product
Vacuum packing	O_2 and CO_2 permeability of packaging film and storage temperature will determine shelf life and type of spoilage
Cooling, <2°–5°C within 8–12 hours	
Storage, <10°C	

Table 18-3 Typical Process for Meat Pies

Process Steps	*Microbiological Importance*
Selection and butchery of raw meat and fat materials	Concentration and types of microorganisms
Tumbling and massage of cuts	Introduction of salt and phosphate; pH modification
Trimming and size reduction	
Mixing, seasoning, and heating of meat mix	Gelling of starch and thawing of frozen meat pieces
Cooking process, typically 100°C for some minutes	Kills vegetative cells and some spores
Meat mix cooling in container	
Indirect cooling to 10°–35°C within 4 hours	Under conditions to prevent recontamination
Dough preparation	Use of scrap dough must be limited to prevent the use of "sour" dough
Dough blocking and resting to make cases	
Filling and lidding of pie cases	
Baking of filled pies, center temperature of product >90°C	Kills vegetative cells and some spores
Air cooling of pies, <2°–5°C within 8–12 hours	High hygiene conditions required to prevent recontamination, especially with molds
Wrapping	Moisture-permeable wrapping used to keep crisp crust and may prevent recontamination
Storage <10°C	To prevent growth of spores and other contaminants

To minimize the chances of surviving spores outgrowing, products should be cooled as quickly as possible after cooking. This must be achieved without freezing the product surface (*typical* maximum cooling times for 2.5 kg joints are <8 hours between 50° and 10°C). Spoilage defects (eg, greening or gas production) or unsafe product may result from the growth of clostridia, such as *C. perfringens*, during slow cooling. This may occur if product units are too large to cool quickly or if inefficient or overloaded cooling equipment is used. After cooling, storage at 5° to 8°C is needed to prevent the growth of psychrotrophic spores, typically *Bacillus* spp., which may cause musty flavors or slime formation after prolonged storage of vacuum packaged products (>10 to 20 days). In EU countries, maximum temperatures during processing meat products are defined by law, eg, in slicing rooms (<12°C, except where a derogation for technical reasons is obtained) and during distribution and retail storage (<7°C). Rapid cooling is also required. If lightly preserved products are cooked and stored at 0° to 2°C in their original primary pack, their shelf life may only be limited by chemical changes (including rancidity and color loss), as recontamination and spore outgrowth are prevented. For most products, shelf life is limited by microbial spoilage or contamination by post-process additions, eg, gelatin and garnishes on pates can further limit shelf life. Such additions may be heat treated to decontaminate them or they may be preserved with acid or salt. The introduction of nondecontaminated material into hygienic areas significantly increases the risks of product recontamination.

Many cooked products are vacuum or modified atmosphere (MA) packaged after slicing or repacking; the shelf life of these is usually less than 28 days under chill storage. Vacuum packaging relies on the ability of the contaminants to remove residual O_2 and produce CO_2, or MA packaging uses gas flushing with N_2, CO_2, or gas mixtures (70% N_2, 20% CO_2, and 10% O_2.) to extend shelf life. The lack of oxygen and the accumulation of CO_2 encourages the growth of the slower-growing acid-producing lactic acid bacteria, and suppresses the growth of the rapidly growing aerobic spoilage flora (typically pseudomonads), which can produce ammoniacal end-products. Therefore, shelf life is limited by the growth and metabolism of LABs. If the pack pH is >5.6, the Enterobacteriaceae can grow and produce putrid spoilage and product blackening from H_2S production.

18.4.3 Raw-Cured Products

The intrinsic preservation feature that gives these products, which are usually pork based, their unique identity is the addition of nitrite and salt, and in some cases air drying. Nitrite and salt react with meat even without heat, giving stable red colors, flavors, and textures.[205] The range of raw-cured products may be subdivided according to a_w and product usage as follows:

1. High a_w products intended for refrigerated storage and cooking, eg, bacon (typical shelf life 3 to 6 weeks)
2. High a_w products for refrigerated storage and raw consumption, for example Teewurst (a minced, raw pork product, typical shelf life up to 1 week)

3. Low a_w (eg, below 0.8) products such as ambient-stable raw, heavily salted, dried hams (eg, prosciutto), bacon, and nonfermented dried sausages (typical shelf life 6 to 12 months)

In EU countries, the maximum legal input level of sodium or potassium nitrite is 150 ppm; an equal amount of nitrate may also be added. Current input levels result in residual levels from 0–50 ppm after storage. In some countries, to prevent excessive addition, they may only be added premixed with sodium chloride. Nitrite addition is controlled because during high temperature cooking (eg, frying of bacon) nitrosamines may be formed by the reaction of nitrite with amines in foodstuffs. Phosphates may be added, principally to enhance water retention, and ascorbate is used to enhance color formation.

Nitrite has wide-ranging antimicrobial activity, inhibiting many sporing and nonsporing microorganisms (see Chapter 19).[14,20,28] It selects for lactic acid bacteria and yeasts, which eventually cause spoilage of these products; yeasts are associated with the spoilage of low a_w products. Its antimicrobial activity is pH dependent and increases as pH decreases (from pH 7 down to 5); nitrous acid is thought to be the inhibitory molecule.[33] Low water activity (*typical range* 0.99 to 0.9) achieved by salt addition (typical salt/water levels are 2.5% to 15%) or drying enhance the preservative effect. The use of multiple factors to control growth is called Hurdle Technology (see Chapter 14).[130,132] Typical spoilage species can grow in products and in-process materials containing nitrite at the normal input levels (150 ppm), in up to 10% NaCl, at high CO_2 (20%) concentrations, and down to 8°C. Many types can produce slime (dextran), for example, in curing brines or on sliced products, and in the presence of O_2, *Lactobacillus viridescens* and *Streptococcus faecium* can cause greening of raw products by oxidation of meat pigments (by H_2O_2 formation). The Gram-negative bacteria typically associated with raw meat are inhibited by nitrite (input level 150–200 ppm) or if the pH of the meat is below about 6.

Nitrite is active against *C. botulinum*; particularly in the presence of sodium chloride.[38,182,187] It is also effective against *C. perfringens* and the cold-growing clostridia.[8,107,183] Toxigenic types of *C. botulinum* differ widely in their resistance to NaCl and NO_2. Type A and proteolytic Types B and F are more resistant than Type E and the nonproteolytic Type B and F strains (see Chapter 41). At 20°C, 10^6 spores of *C. botulinum* Type A and B sample did not produce toxin in nitrite-free bacon, whereas at 30°C, 10^4 spores grew to produce toxin in nitrite-containing bacon.[38] The precise mechanism of action of nitrite on microorganisms in meat products is unknown. It may inhibit by reacting with either amino groups, sulfydryl compounds, or with the pyruvate-ferredoxin oxidoreductase in the phosphoroclastic reaction; the latter reaction is used during the initial stages of spore outgrowth.

High a_w *Products*

In bacon, the low salt level (now generally below 3% salt-on-water [s/w]) and slightly acidic pH (pH 5–6) determine the type of microbial growth and spoilage. The use of oxygen-impermeable films with MA packing slows the loss of color and the growth of the aerobic spoilage flora, promoting the growth of salt-tolerant facultatively anaerobic species such as streptococci, leuconostocs, pediococci, lactobacilli, and some vibrios.[79] Depending on the temperature, pH, and a_w, the microflora may exhibit lipolytic activity against triglycerides or proteolytic activity against peptides and proteins or form hydrogen peroxide and organic acids and other metabolites (eg, dextrans and acetoin) from carbohydrates. The streptococci, micrococci, lactobacilli, and leuconostocs dominate the spoilage flora of low-salt bacon and similar products with pH values below 5.4.[229] If the pH is above 5.5–5.6, then the facultatively anaerobic Enterobacteriaceae take over and their growth may cause sulfide spoilage (blackening). In 1982, Gardner[78] reported that vacuum packed low-salt bacon (<7% s/w) soured at below 20°C because of the action of lactic acid bacteria; at 30°C, growth of Enterobacteriaceae caused it to become putrid. During the storage of high-salt bacon (*ca.* 10% s/w) at 20° to 30°C, the micrococci, leuconostocs, and coagulase-negative staphylococci grew and produced a cheesy spoilage. Since 1982, salt levels have dropped and 2% to 3% s/w is now common. If salt concentrations are maintained at 3% to 4% s/w, low input levels of nitrite (50 ppm) may be sufficient for the technological needs (color retained and spoilage inhibited) provided the bacon is stored below 10°C.

Because salt levels are low in commercial bacon, microbial growth is largely controlled by temperatures during curing, processing, storage, and distribution. Vacuum packaging of the sliced product extends the shelf life to 3 weeks or more at 3° to 10°C by selecting the spoilage flora and slowing its growth. The O_2 permeability of the film used plays a major role in determining the composition of the spoilage flora and the shelf life; the lower the O_2 and CO_2 permeability the longer the shelf life. In vacuum packs, the spoilage flora grows more quickly on the "fat" (micrococci, streptococci, and lactic acid bacteria—lactobacilli, pediococci, and leuconostocs) than on the "lean" (mainly lactobacilli). But it is growth on the lean, accompanied by the breakdown products of protein/peptide metabolism that leads to spoilage; higher salt levels favor growth of the leuconostocs, which have weak proteolytic activity. Breakdown of the cured pigments by microbial action gives green or brown colors, usually prior to slime formation, and is the typical form of spoilage. The assurance of minimum customer cooking time and temperature by provision of microbiologically validated cooking instructions is essential for product safety.

Low a_w *Products*

The low a_w of these products, such as dried hams and sausages, selects for the more a_w-resistant types of lactobacilli, micrococci, microbacteria, enterococci, leuconostocs, and yeast and molds. Depending on the preservation system, products may be chill stored (typical closed-pack shelf life 7 to >200 days at 7° to 10°C) or be shelf stable. All have typical microfloras, which develop during storage; differences are largely determined by a_w and packaging. Dry-cured ham stored in air supports the growth of micrococci[209] and yeasts. The survival of infectious pathogens, such as salmonella, verocytotoxic *E. coli*, and *L. monocytogenes* in these products is the major microbiological safety hazard,[196-198] and may lead to illness.[30] In dry-cured hams, the formation of staphylococcal enterotoxin has not been detected in products with an a_w of <0.89 at 35°C but was found in a product with an a_w of 0.92 at 20°C.[226] Enterotoxin production in these products has been found when the competing flora is suppressed, for example, by surface scalding followed by contamination with *S. aureus* by human handling. Smoking may also be part of the preservation process, carried out as part of surface drying and leading to deposition of anti-oxidant and antimicrobial compounds on the product surface.[18] The type of wood used to provide smoke and the smoke-generating equipment used must be carefully controlled to minimize the chances of carcinogen production during processing. After drying a high standard of hygiene during handling and slicing is essential to prevent contamination with a microflora well adapted to growing on the product, and within the pack, and capable of causing premature spoilage. The primary packaging materials have two functions, to limit the chances of product recontamination after processing and to limit the uptake of moisture during storage. Where vacuum or MA packing is used, the films used should be able to retain a nitrogen gas atmosphere, rich in CO_2, to reduce the growth rate of, or suppress, aerobic spoilage microorganisms, especially molds.[129] High CO_2 (20%) atmospheres may be used in gas-flushed packs for sliced products, to prevent the slice adhesion caused by vacuum packaging, but choice of a packaging film with low O_2 permeability is always essential to retain quality and prevent rancidity.[165] Although this packaging is mainly done to preserve the appearance and taste of products, it may also be done to minimize the chances of mycotoxin formation, because a high percentage (78%) of molds from these products have proven to be potentially toxigenic.[135]

Microbiologically Important Features of the Manufacturing and Formulation Technology

Products may be whole joints, such as legs, or prepared from muscle pieces, minced, or comminuted meat. Contaminants remain predominantly on the outside of whole joints, especially if dry curing is used. They may be carried into the muscle by butchery, within bone, or redistributed by comminution or by liquid-curing equipment, especially by the recycling of "injection" brines from multineedle or other injection equipment. The rate of curing is dependent on the rate of diffusion and the intramuscular distances involved. If curing salt does not reach the center of the side, especially the "pocket" of the scapula or other deep muscle and reduce the a_w, then bone taint may be caused by growth of contaminants (eg, alcaligenes, proteus, or clostridia) that are normally inhibited by the high salt concentration (7% to 10% s/w). When chilling prior to salting is ineffective, or process times before effective curing are too long, spoilage similar to that of raw meat held under similar conditions may occur. Processing conditions are less severe than are used for traditional dry hams (see below), and there are differences in the salt tolerance of microorganisms growing as a result of undercuring.

High a_w *Products for Cooking (eg, Bacon)*

Bacon may be cured using brine or by the dry application of crystalline salt; a typical process for commercially produced brine-cured bacon is shown in Table 18-4.

The types and number of microorganisms in a curing brine will vary with its salt and nitrite/nitrate content, its age, the hygiene of tanks, etc, and the initial condition of the meat placed in it. A traditional production method of bacon production, Wiltshire cure, involves the immersion of sides of pork and/or pump-

Table 18-4 Typical Process for Low-Salt, Smoked Bacon Manufacture

Typical Process Stages	*Microbiological Importance*
Carcass preparation—stunning, exsanguination, scalding, dehairing, scraping	Contamination of carcass with pathogens
Evisceration and splitting of carcass	Contamination of meat with pathogens
Grading of meat	
Chilling; 4° to 5°C within 12 hours	Prevent growth of mesophilic pathogens
Trimming of sides	
Injection with curing brine, >8% by weight, >18% salt + 0.15% sodium nitrite	Prevent growth of anaerobic pathogens, eg, clostridia
Filling tanks with cover brine (*ca.* 20% salt + 0.15% sodium nitrite)	Allow development of typical microbial association of salt-tolerant bacteria
Holding in tanks at *ca.* 5°C, 2 to 5 days	
Drainage and cooling	
High temperature/short time smoking (60°C for 2 to 4 hours)	Some reduction of surface contaminants
Cooling to 0°C	
Slicing and vacuum packaging	Recontamination with adapted spoilage flora; O_2 and CO_2 permeability of packaging films will determine shelf life
Storage	Temperature will determine shelf life

ing them with brine by injection, followed by draining and maturation. Although brines are usually chilled to preserve them, they can contain very high numbers of vibrios, aciduric lactic acid bacteria, enterococci, and micrococci (especially in brines >3 months old).[78,79] Many of the spoilage species associated with raw meat (eg, pseudomonads) are inhibited and die out at the high level of salt (up to 20%) in brines. Modern bacon curing generally uses clean brines and the flora present on the bacon therefore reflects that of the meat and is numerically less and less diverse. In bacon containing 6% s/w, *S. aureus* produced toxin at 27°C but not at 15°C.[200]

High a_w Products for Raw Consumption (eg, Teewurst)

The manufacture of traditional, spreadable, high a_w products, such as Teewurst, which are eaten raw, may or may not include a short fermentation stage (2 to 3 days), to reduce the pH to *ca.* 5.3–5.5 and produce a typical flavor; a typical manufacturing process is shown in Table 18-5. These mildly preserved products have a short shelf life, of about 5 days at chill. Spoilage is caused by the lactic acid bacteria and quality loss is taken as loss of color. They may contain infectious pathogens, such as salmonella and *L. monocytogenes*, because processing and storage do not reduce numbers. They have their origins in a time before agricultural systems based on intensive husbandry increased the incidence of infectious pathogens, such as salmonellas in meat. Currently, it is assumed that the level of infectious pathogens in the raw materials is still low enough to ensure product safety, without any decontamination. However, it is difficult to regard these products as microbiologically safe in view of the the known incidence of infectious pathogens in pork.

Low a_w Products (Dry-Cured Hams, Bacon, and Nonfermented Dried Sausages)

Traditional dry-cured hams are made from whole primal joints dry salted on the outside; salt is applied to the interior, around any bone present (a typical process for dry-cure ham is shown in Table 18-6). Initial processing and storage is generally below 10° to 12°C,[144] in air for a period of some weeks; higher temperatures (20° to 25°C) are used to complete the

Table 18-5 Typical Process for Teewurst

Manufacturing Stages	*Microbiological Importance*
Select and trim chilled pork pieces	Initial level of pathogen contamination will determine safety of product
Mince	Contaminants from one carcass may contaminate others
Blend with dry ingredients, including 0.15% sodium nitrite and salt (minimum a_w 0.95)	
Ferment, using starter, pH <5.3 within 3 days, 15° to 20°C	To provide small reduction in numbers of infectious pathogens (ie, 1 log) and prevent growth of *Staphylococcus aureus*
Portion and pack	
Chill, to below 7°C	
Store and distribute at 5°C; maximum 5 days	

Table 18-6 Typical Process for Production of Dry-Cured Ham

Manufacturing Stages	*Microbiological Importance*
Select and trim chilled pork legs and shoulders	Initial level of contamination will determine safety of the product
Remove bone	
Pack bone cavity with dry crystalline rock salt (contains sodium nitrate) or dry-curing salts	Low a_w interior of joint to prevent microbial growth
Refold meat, to give shape, and tie; rub the surface with dry crystalline rock salt or curing salt	
Dry, initially at <10°C (until the a_w is <0.96), then at a temperature up to 25°C for about 28 days, to give low a_w (eg, 0.7–0.9) depending on stability required	Initial drying is at low temperature to inhibit growth of pathogens
Wash off excess salt and dry at <30°C	Excessive washing will allow a rise in a_w and favor spoilage; high drying temperature may allow growth of *Staphylococcus aureus*
Net wrap or vacuum pack	Net wrapping is suitable for products with an a_w of approx. 0.7; vacuum packing of higher a_w products will prevent growth of molds
Store and distribute, ambient temperature for products with a_w approx. 0.7; chill temperature for products with higher a_w	Temperature changes can promote condensation in vacuum packed products and thus cause spoilage

drying process, after drying to an a_w of less than 0.96. Poor initial cooling of joints, after slaughter, and slow curing or a_w reduction may allow the growth of contaminants eg, *Arthrobacter*, corynebacteria, *Bacillus*, *Sarcina*, and *Aerococcus*.[30,107] As there is no heating during processing, salting and rapid drying to give a_w below about 0.95 is essential to prevent the growth of pathogens[140,190]; the final a_w of raw ham is 0.7–0.8. Slow rates of preservation (weeks rather than hours) and cool temperatures allow survival of *S. aureus* or *C. perfringens* in these and other dry products.[95] To prevent the outgrowth of clostridial spores, the rate of a_w reduction and chilling and holding temperatures must be linked, so that conditions within the joints remain outside germination and outgrowth limits of spore formers. A predictable level of unbound nitrite during processing and shelf life is essential for safety and to prevent spoilage; for typical input levels, *ca.* 150 ppm, residual levels of 10–50 ppm are common. Some hams are preserved only by the use of sodium chloride (12% to 15% w/v) but the salt used contains sodium nitrate, which is reduced by the microbial flora to nitrite. This combines with the meat pigments to give the typical cured color of raw ham. There is a strong interplay, protective or otherwise, with humectants such as salt and proteins and the spoilage flora. Thus, the survival or growth of *S. aureus* in dried sausages may depend on the growth of lactic acid bacteria during processing.[155] Poor hygiene during manufacture will allow the growth of salt-tolerant microbes, such as micrococci,[158] in equipment, and these may be introduced onto the product during curing or by handling. Poor temperature control when hams are washed to remove excess salt may lead to the growth of *S. aureus* and other organisms.[226] The formation of bacterial slimes on these products during storage is rare and the surface flora is dominated by molds (eg, *Aspergillus*, *Monilia*, *Oidium*, *Fusarium*, *Mucor*, and *Penicillium*),[134] including toxinogenic species.[191] Trichinae may also be a hazard in dry-cured hams, but may be eliminated by storage at 24° to 35°C for periods of time depending on size of the ham.[139]

Bacon may also be manufactured using a dry-curing route. Because of the low a_w, its microflora is dominated by salt-tolerant micrococci, yeasts, and molds, similar to dried hams. On slicing, contaminants from the outer surface may be redistributed on the faces of each slice; shelf life is limited by the extent of growth that leads to unacceptable quality changes.

The key microbiological mechanisms at work are inhibition and selection by reduced water activity, salt and nitrite, and restriction of growth by storage temperature. Because low water activity is a key preservative, surface uptake of water may cause localized spoilage; for example, if there is condensation on a cold surface when product is moved from a chill to an unchilled area. Prolonged frozen storage may cause rancidity in these products.[179]

18.4.4 Cooked, Cured Products

These products include cooked hams, comminuted pork products, and pates with closed-pack storage life under chill of up to 2 months (ambient-stable canned products have a shelf life of over 12 months). The preservation system is complex but is principally the combined effect of heat and curing salts (ie, sodium chloride and nitrite) and storage temperature; the nitrite provides the characteristic color of cured products by forming nitroso-compounds with myo- and hemoglobin. The minimum heating process used depends on the intrinsic preservation system and the intended storage temperature. Pasteurization (60° to 80°C) will eliminate all vegetative cells, but does not kill spores. Hence,[75,76] the combination of salt and nitrite in the product and the storage temperature must prevent their growth. The more severe processes (100° to 110°C) used for shelf-stable canned products cause a limited additional reduction in spore numbers and injure the survivors, limiting their ability to outgrow, especially in the presence of nitrite and salt.[92,166]

The most severe microbiological hazard associated with the ambient-stable products is toxin production by growth of *C. botulinum* from spores surviving the heat process or contaminating the product after processing.[93,96,182] Hauschild and Simonsen[92] considered that the botulism risks were controlled by a combination of the low incidence (*ca.* 1 spore kg^{-1}) of *C. botulinum* in the raw materials and the effects of thermal injury in the presence of salt and nitrite on these spores. In cooked products, nitrite is particularly effective at inhibiting the germination and outgrowth of clostridial spores,[157,182,187,215] an effect that is enhanced by chilled storage.[184,185,186] To be effective in ensuring microbiological safety, there must be sufficient nitrite at the beginning of processing to ensure the presence of free or unbound nitrite during and after cooking (typical input levels of *ca.* 150 ppm), and minimum effective residual levels *ca.* 5–10 ppm are needed to inhibit the germination and outgrowth of *C. botulinum* spores.

Heating (>90°C) is believed to enhance the effectiveness of nitrite in two ways. First, it promotes the direct reaction of nitrite with spore components thought to be involved in outgrowth, and second, it causes the formation of inhibitory compounds by reactions with iron-containing compounds in meat.[174] Because the formation of these so-called Perigo factor compounds is so variable, and because there is doubt whether they play a significant role in the safety of cured meat products, their inclusion as a quantifiable part of the cooked cured meat preservation system is not possible.[175]

The antimicrobial effects of nitrite are enhanced by reduced water activity (<0.98). This can result from the addition of salt or other humectants or the solubilization of low molecular weight meat components.[82] Roberts and Gibson[184–186] carried out a series of experiments examining the antimicrobial effects in pork slurries of heat treatment, pH (5.5–6.3), nitrite, and salt level. They concluded that increasing nitrite level did not affect spoilage, but controlled growth of and toxin production by *C. botulinum* Types A and B up to 15°C. The effect was increased by higher heat treatment, salt level, and the presence of ascorbate and lower storage temperature.[185] The use of other agents, such as phosphates, has been investigated as a means of achieving stability of "mild" products.[141] Gamma-irradiation (3–4 kGy) has also been tested as part of a combination preservation system for cooked cured meat products.[70,72]

Microbiologically Important Features of the Manufacturing and Formulation Technology

Chill-Stable Products. These are made using mild heating processes with coldest point temperatures of 60° to 85°C. Minimum time/temperature combinations are usually above those required for cooking to ensure that the products are free of infectious pathogens. Because the product units cooked are often large (eg, 12 x 15 x 60 cm), process times of 6 to 8 hours at oven temperatures 67° to 75°C are necessary to allow heat penetration to the center of the product. There is a slow rate of heating because of the small temperature difference between the product target temperature and the oven temperature; this is necessary to prevent the cook-out of gelatin. This means that much of the killing is done at low temperatures of 50° to 60°C, where its kinetics are poorly understood. The vegetative microflora is destroyed, but the majority of the bacterial spores remain viable. However, heat interacts with nitrite to inhibit surviving spores.[166] Because product yield is maximized by the use of the lowest possible heat process, the survival and growth of unusually heat-resistant vegetative cells may occasionally cause spoilage, for example, by the ropy-slime producer *L. viridescens*[76,142] or by streptococci. This type of spoilage may occur when high temperatures (>15° to 20°C) occur during raw material transport, storage, or the curing process and have allowed microbial numbers to exceed 10^6 g^{-1}.[143] To remedy this, heat processes may have to be increased if there is a build-up of heat-resistant species, such as enterococci.[168] Spore outgrowth will be affected by the rate of cooling after heating and rapid cooling to 8°C increases stability.[113] The length of time between 55°C and *ca.* 20°C should be limited to 2 to 4 hours to prevent the growth of mesophiles and activation of spores, and further cooling from

20°C to 5°–10°C should occur within 8 to 12 hours. Slow cooling to temperatures above 20°C may lead to the outgrowth of spores of *C. perfringens*, especially in containers providing anaerobic conditions, such as in clamps or vacuum packs.

When products are removed from the containers used for their cooking, repackaging, slicing, portioning, or resale, the major hazard is recontamination. Only products cooked and stored in the same hermetically sealed container will be shelf stable or stable for prolonged periods at chill temperature (eg, 6 months at *ca.* 3°C), because recontamination is prevented. Various methods have been investigated and used for decontaminating open packs including the use of a hot water dipping, steam,[42] and acid treatment.[167] The fate of any contaminants introduced after cooking will be determined by the intrinsic preservation system[68] and conditions of storage. For instance, in mildly cured vacuum packed product stored at 24°C, numbers of salmonellas increased from 100 to 1 million g^{-1} over 6 days, whereas below 15°C their numbers did not increase.[45] *Staphylococcus aureus* from the hands of food handlers may contaminate products and at temperatures above 10°C may grow and form enterotoxins. Other pathogens such as *L. monocytogenes* may be picked up from equipment or cooling facilities and grow at chilled temperatures[55,202] and cause illness.[150] Many methods have been proposed to protect products from pathogen growth. For example, reduction of the a_w from 0.993 to 0.96, pH reduction from 6.9 to 5.9,[55,201] high CO_2, salt, and nitrite levels and low pH with additional chemical preservatives, such as lactate, sorbate, or nisin,[25,29] have been proposed to prevent growth of *L. monocytogenes* during chilled storage.

The most common post-process contaminants are spoilage types, because they are most numerous in the processing area or on equipment. In sliced, vacuum packaged luncheon meats, storage temperature will determine to a large extent whether spoilage is caused by lactic acid bacteria or by *B. thermosphacta*,[60] the latter being favored by lower temperatures and the presence of nitrite.[169] Both species may be found in slicing areas and the risk of contamination is controlled by process hygiene, which includes use of a forward-flow process layout, the segregation of personnel handling raw and cooked products, and implementation of operating procedures designed to prevent cross- and recontamination after cooking.[36] If there is poor separation of raw and cooked material during retail sale, especially if products are unwrapped, then contamination with infectious pathogens such as salmonella, verocytotoxigenic *E. coli*, or *L. monocytogenes* can occur.[85,104,159] This type of product is often sold sliced, and slicing and vacuum packing within the manufacturing environment, rather than at a retail outlet, offers the best chance of preventing recontamination, because segregation and hygiene procedures are easier to control. The film or web materials used for vacuum or modified atmosphere packaging (MAP) and the equipment used must give high degrees of seal integrity and low permeabilities for CO_2 and oxygen, to contain the gaseous atmosphere,[46] which reduces the growth rate of spoilage microorganisms.[57] Modified atmosphere packaging using carbon dioxide as the atmosphere generally encourages the growth of lactic acid bacteria, such as leuconostocs,[56,58,121] and suppresses the growth of the aerobic Gram-negative bacteria on this type of product. *Yersinia enterocolitica* will survive in chill-distributed frankfurter-type sausages.[6]

Ambient-Stable Products. Where there is a requirement for ambient stability, fractional F_0 or full sterilization processes are normally used. The choice of heat process should be governed by the spore challenge from the raw materials[92] and the concentration of curing salts used.[108] Thus, the higher the initial concentration of spores in the raw materials prior to heat sterilization, or the lower the concentration of curing salts, the higher the heat process that should be used to achieve microbiological stability. Unbound nitrite at the end of the heat treatment is essential for microbiological stability. Ascorbate is used to reduce nitrite losses during processing and storage,[145] but some ingredients, such as MRM, which may have a high iron content,[117] may increase nitrite loss.[47,48] Other ingredients, such as soy protein, may also reduce the effectiveness of nitrite.[114] If the input levels of salt and nitrite are high (nitrite > 150 ppm + salt/water >3.5%), then it is possible to use a fractional F_0 process (typically 0.05–0.86, but up to 1.5), giving limited log reductions of *C. botulinum* (<2.5D). In some countries the risks associated with these low heat preserved products are increased by the consumers' wish for low salt (<3.0% s/w) (and therefore low nitrite) products. Such salt-on-water levels in the presence of low residual nitrite (<5 ppm) are insufficient to inhibit the growth of *C. botulinum* and other clostridia, under ambient storage conditions. To minimize the chances of spoilage and to provide a good margin of safety, higher minimum processes (F_0 *ca.* 1.5–3.0) should be used for low-salt and/or low-fat ambient-stable hams and luncheon meat–type products.

After cooking, products are cooled rapidly to inhibit spore germination and to limit the adverse effects of heat on texture and cook-out of gelatin. Because spores may not have been killed in sufficient numbers by the temperatures and times involved in cooking, rapid cooling is essential to prevent their repair, germination, and growth. This allows them to overcome the stabilizing effects of the preservation system. The length of time for initial cooling from process temperatures (*ca.* 105°C) to about 65°C is usually rapid. If cans are cooled by a water shower in a retort, then exit temperature should be sufficiently high to promote drying, by evaporation (>45°C), but low enough to prevent can distortion by internal overpressure. Holding time between 55°C and *ca.* 20°C should be limited (*ca.* 8 hours) to prevent spore repair. Hygienic handling of cans after heat processing is essential to prevent post-process contamination of the can contents.[36,194] The water used for cooling the containers after heating must be decontaminated to prevent pack recontamination; this is usually done by chlorination (*typically* 0.2–5 ppm free or residual Cl_2). Measures to prevent recontamination include the use of clean, segregated areas, which are free of non–heat-treated food materials and personnel who may have been in contact with such materials. To minimize risks of recontamination, the post-process areas need to be maintained to very high standards of hygiene by the regular cleaning and disinfection of the environment and equipment. These products are usually sold in their primary packaging or vacuum pack bags, although they may be unwrapped after storage for slicing, etc. Once the primary pack has been opened, it should be treated as chill stable. A typical process for the manufacture of canned luncheon meat is shown in Table 18-7.

Table 18-7 Typical Process for the Manufacture of Canned Luncheon Meat

Process Stages	*Microbiological Importance*
Selection of raw materials including meat, fat, MRM, and blood	The bacterial spore load (max level of spores should be 100 g^{-1}) and the ability of the meat mix to bind nitrite
Size reduction and emulsion formation, addition of salt (*ca.* 2.5%), nitrite (150 ppm), ascorbate and stabilizer (eg, disodium diphosphate)	Formation of intrinsic preservation system
Mixing of additional dry ingredients, cereal	
Chilling	To give viscosity required for filling
Filling into cans	Weight control to achieve effective and consistent thermal process
Vacuum closing and can seaming	To prevent contamination of contents
Thermal processing and cooling of cans	Fractional F_0 0.15 (process temperatures *ca.* 105° to 110°C) customarily used; for low-salt products (<3% s/w) an F_0 1.5–3 process should be used and cooling to 20° to 30°C should be complete within 10 to 12 hours. Residual level of nitrite 5–10 ppm
Post retort can handling	Prevent recontamination of wet cans through their seams
Storage	Products are designed for storage <25°C

18.4.5 Commercially Sterile Meat Products

Typical products are canned meats and meat-containing soups sterilized in cans, jars, or pouches. They may also be in-line sterilized and then aseptically packed. These products can support the growth of most pathogens because they do not contain an intrinsic preservation system, thus commercial sterilization is required. The heat processes used are at least equivalent to 3 minutes at 121°C, ($\geq F_0$ 3), the minimum mandatory requirement for safety in many countries, and considered sufficient to cause a 12-D reduction in numbers of *C. botulinum*. Commercially used processes (eg, $F_0 \geq 5$–8) are usually above this minimum to eliminate the more heat-resistant spores of species able to cause spoilage at temperate (<35°C) storage temperatures. Packs of these products may be either conduction or convection heated, which affects the rate of heat penetration. In addition, they may not heat uniformly if they contain mixtures of particles and liquids, therefore solid-liquid ratios should be specified. Other process and product factors can also affect the rate of heat penetration. Major variables include the product temperature at the start of the thermal process, eg, frozen particulates which may be used and the effect of these on the initial temperature of the product at the commencement of the report cycle must be determined.[193] Also the effect of ingredients on product viscosity must be determined. Unpredictably high viscosity can reduce the rate of heat penetration, and hence the heat treatment received for particular process conditions. Compositional factors, such as high oil levels in emulsified products, may reduce the lethality of heat processes by increasing spore heat resistance in a low a_w environment or causing increased tailing of survivor curves.[80] Usually the heat processes used for meat products are not sufficient to ensure that they are completely free of the heat-resistant spores of thermophiles. Severe sterilization processes (F_0 15–35) are required for their elimination; and these treatments are likely to have a marked detrimental effect on product quality. The risks from thermophile spoilage (caused by *Bacillus* or *Clostridium* spores) are accepted as low in meat products, because their occurrence in sufficient numbers to survive standard heat processes is rare, even in flour and spices ingredients.

Microbiologically Important Features of the Manufacturing and Formulation Technology

The most important preservation features are the designated minimum heat process ($\geq F_0 = 3$), and prevention of post-thermal processing recontamination by an assured level of pack integrity, hygienic handling post-thermal processing, and prevention of pack damage. To meet the designated process reliably, it is essential to use containers and sterilization equipment with predictable heat penetration and heating characteristics and to control filling and sealing procedures. Hygienic cooling and prevention of manual handling of processed containers while they are warm and wet is essential to prevent spoilage by recontamination. The equipment used for handling containers must not damage them and must be hygienic. For further information on the thermal processing of food see Chapter 3.

18.4.6 Low and Intermediate a_w Products

These products rely mainly on low water activity for stability during ambient storage (typical shelf life is 12 months). They include those traditionally made without heating (eg, sun- or air-dried meats; $a_w < 0.6$) or those produced industrially, often with mild heating for setting the proteins, followed by air, spray, or freeze drying (typical moisture contents of <5%, a_w <0.1). Meat extracts (typical a_w <0.8) are also produced from bones, etc, by very high heat rendering treatment (>130° to 140°C) and evaporation plus salt addition (>12% to 20% salt) to provide stability. Intermediate moisture meat products may be made using a variety of humectants; examples of such products are described in Chapter 14.

The microflora surviving in mild-heated products (such as air-dried meats) includes Gram-positive, catalase-positive cocci, eg, staphylococci and micrococci.[122,190] Pathogens such as *S. aureus* and salmonella may also survive mild heat (<50°C) drying processes, but may die out during storage.[120] Freeze drying causes little or no reduction in microbial numbers. Meat products produced by high temperature rendering are usually sterile, and any microorganisms present will be factory contaminants, eg, halo-tolerant species such as yeasts and molds. Hence, rehydration during storage or use can lead to products becoming moldy.

To allow air drying within a short time, meats in industrial processes (Table 18-8) are usually broken

Table 18-8 Typical Process for an Industrial Dried Meat Product

Process Stages	*Microbiological Importance*
Selection of meat pieces	Initial concentration of pathogens
Trimming and removal of fat and bones	
Pre-breaking and flaking of meat	To provide small particles (*ca.* 5 mm) capable of rapid a_w equilibration
Preparation of stock from bones (100° to 140°C for 3 to 4 hours)	Stock is usually sterile unless recontaminated during the downstream process
Blending of meat flakes and stock	
Low temperature (50° to 60°C) heat setting of proteins in stock solution	Temperatures only provide minimal pasteurization
Drying by evaporation, cooling, and cutting to give particulates	May lead to recontamination (equipment and environment); effective and uniform drying for initial reduction of a_w is essential
Final air drying of particulates (typical maximum process temperature 75°C)	Low a_w (*ca.* 0.1–0.4) may give increased heat resistance to pathogens
Milling of dry particulates	May lead to recontamination, as complex pieces of equipment are difficult to clean and if wet cleaned, difficult to dry
Filling into moisture-proof bags	Maintenance of low a_w by pack integrity

down into small particles (<5 mm) or in the production of traditional dried meat products such as Biltong into very thin strips having a similar maximum thickness; control of size and hence drying rate is critical to safety. Because of the complexity and scale of the industrial scale plant used, effective control of hygiene and the prevention of cross-contamination is difficult. It is a major decision whether microbiological safety is best protected by the use of wet cleaning and disinfection procedures on plant equipment known to be difficult to clean and dry, or whether dry cleaning methods will give a lower overall risk, because growth is prevented. Where continuous processes are used, "in-process" material often has a substantial range of residence times and moist material may be held up for potentially hazardous periods at growth temperatures. Therefore equipment should be designed and controlled to minimize the build-up of materials and long drying times at temperatures allowing microbial growth.

Microbiologically Important Features of the Manufacturing and Formulation Technology

Dehydration, drying, or addition of humectants (eg, salt, glycerol, and sugars, may be used for intermediate a_w products) are used to reduce the a_w to <0.85 or usually to <0.6. Inhibitory water activities must be achieved sufficiently quickly to prevent microbial growth and toxin formation. Heat used for setting process (Table 18-8) should be sufficient to destroy likely levels of infectious pathogens present in raw materials. After heat processing, cross- and recontamination must be prevented. The design and operation of continuous processes must ensure that these are suitable means of preventing the fastest moving materials within the main product flow receiving less than the time and temperature required for proper drying. Dried meats are hydroscopic, hence their primary packaging must be done as soon as possible after processing. Where containers or packs are incompletely filled, or there are temperature fluctuations during storage, a_w may increase because of condensation and product rehydration, and mold growth may occur within the pack. This may be minimized by reducing the head-space volume and the risks of mold contamination minimized by hygienic filling. If foods are formulated with ingredients of different moisture contents, or packaged with an inadequate moisture barrier, moisture migration or uptake will raise the a_w to levels allowing spoilage.

18.5 CONCLUDING REMARKS

18.5.1 Manufacture and Product Use

The scale of industrial manufacture of meat products increases year after year with the elimination of many low capacity and small-scale local producers. This offers opportunities for more consistent quality and safety standards via improved control, but reduces the availability of many traditional and specialized meat products. The consequences of any undetected loss of process control during the large-scale manufacturing and wide distribution of large batches of product may have far-reaching effects. Because of the scale involved and the increasingly wide geographical distribution of products, remedial actions, such as product recall, are complicated and impose a requirement for a high level of traceability. The use of global manufacturing (meat products for Europe may be made in South America and the Far East) and multistage distribution systems makes retention of batch integrity and control of the distribution chain difficult. Recognition of the need to limit risk to customers and businesses has lead to increased legislative requirements for producers to apply HACCP, to maintain full processing and distribution records,[192,194,210] and to use product coding allowing good traceability of batches.

Historically, public awareness of food safety, in terms of knowledge of pathogens and safe cooking practices, has not been found to affect customer behavior.[149] Generally, processed meat products, particularly those packaged as a meal or meal component, are considered by consumers as safe and ready-to-eat, and that the purpose of cooking is solely preparation for eating. However, where meat products appear obviously uncooked, and there is sufficient publicity and clear labeling with validated cooking instructions, customer attitudes toward the importance of cooking are, according to some recent surveys in the UK, improving. This is despite the fact that the majority of consumers do not read cooking instructions and do not know the correct temperature for the storage of chill-stored foods. There continues to be a need for more consumer education and hygiene awareness information. The manufacturer may apply a process that changes the surface characteristic of a meat product such that it appears cooked, eg, flash frying. Such products are particularly dangerous because, although they may appear cooked, they are essentially a raw meat product.[225]

Opportunities to manufacture more mildly processed, but microbiologically safe, meat products are provided by the improved ability to operate manu-

Next Page

facturing processes close to their "limit values." Microprocessor (PLC) controls allied to multipoint measurement in process equipment allows more accurate and reliable process control than is possible with single point measurement and manual controls. Such improvements allow less separation between the operating targets and limits. Reduced heating conditions are also possible where ovens and retorts can work accurately (± 0.5°C) and reproducibly (no loss of performance over 10,000 operating cycles). Preparation equipment (dosing equipment, fillers, mixers, etc) can give products with very consistent and predictable heating characteristics. Many manufacturers and retailers also rely on their ability to limit contamination of decontaminated products by the use of hygienic slicing and packaging areas for chilled ready-to-eat products.[36] Control of the chill chain to low temperatures (0° to 5°C) slows spoilage and limits the growth of most pathogens. Although there may be improved chill chain handling during distribution, there is no evidence that storage temperatures in the home have been reduced to a similar extent. Increased risks are associated with poor temperature control during domestic storage, which may be the majority of the product's shelf life, and the demand for long "use by" periods increases these risks. Modeling studies may be used to simulate the effects of storage or system failures, and HACCP studies are the only approach for ensuring that these and other risks are adequately considered.

18.5.2 The Use of HACCP and Predictive Models

HACCP is increasingly used internationally by meat product producers to predict hazards and to reduce the risks of products causing foodborne illness.[123,144,192] The use of structured hazard analysis to provide a focus for HACCP studies and the use of data from line audits in these studies and their reliable implementation as management and control systems will significantly improve product safety.[15,27,223] At present, assurance of raw material quality and implementation of HACCP studies based on sound data and expert knowledge of microbiological hazards and their control during production and manufacturing processes are the weakest link in the chain of risk reduction. HACCP studies should be based on line audits and must define requirements in the context of actual process capability. Statistical process control techniques are becoming widely used for assessing their value. Unless the validity of a HACCP study and the quality of its implementation are regularly reviewed, newly identified foodborne pathogens (such as *E. coli* O157:H7) or altered or unexpected hazards (such as ingredients like MRM that bind nitrite) may be missed. As better support tools become available to microbiologists, such as predictive models or epidemiological data, the identification of realistic hazards will improve. The necessity for good HACCP studies in capital and labor-intensive processes, such as those used in meat product manufacture, is increased by continuing pressure to reduce manufacturing costs, especially the *indirect* costs associated with the control or assurance of quality and safety, while maintaining or reducing levels of risk to consumers.[23,210]

Simple D and z models have been used for more than 50 years to predict the lethality of heating processes and to answer "what if" questions concerning the impact of changes in time and temperature during heat processing on the chances of survivors (see Chapter 3). However, these models do not take account of the nonlinear death kinetics often observed. Models based on an understanding of the biological mechanisms involved could allow better design of heat processess to control spoilage and ensure safety. Many mathematical models predicting microbial growth[148] are now available (see below) but few on microbial survival. They can be used for reducing development costs and managing risk, because they allow the user to predict the likely performance of preservation systems in meat products, relying on a combination of intrinsic (eg, low a_w, nitrite, preservatives, or acid) and extrinsic (eg, heat, modified atmosphere, or storage temperature) preservation factors without doing numerous challenge studies. Improved accessibility of models for product developers and the incorporation of an "expert" or at least user-friendly front end would improve their rate of usage.

Because of the complexity of the interactions involved, it is often difficult to pinpoint the critical synergies in preservation systems and predict the effect of ingredients in combination or with nutrients, especially under marginal or stress conditions. Models can be used for identifying the likely critical relationships controlling spoilage or safety hazards, by integrating the effects of temperature fluctuations during cooling, distribution, retail display, and home storage.[26,88,124,169] Mathematical models are available for the major spoilage and pathogenic types and for many of the intrinsic factors (eg, pH and a_w) associated with meat products. These include the following: models of the effect of various parameters on the growth of Enterobacteriaceae and clostridia[12]; *Listeria monocytogenes*[25,68,100,101,103] (a survival model[235]); *Escherichia coli* O157:H7[28]; *Clostridium botuli-*

num[188,189]; and *Yersinia enterocolitica*.[218] A prerequisite for accurate predictions is definition of all the critical physical and chemical product variables. Only when this is done can accurate predictions of growth or toxigenisis under the boundary conditions be made, as there are likely to be differences between model predictions (usually fail-safe) and the real situation in food. Significant interactions between microorganisms may reduce the accuracy of model predictions, eg, *Y. enterocolitica* and *L. monocytogenes* are both additionally inhibited by other contaminants in meat products.[103] Model predictions based on the use of laboratory media need to be validated in appropriate food products (see Chapter 16).

18.5.3 Emerging Pathogen Concerns

The emergence of newly identified[51,53,54] or adapted pathogens with enhanced resistance to existing preservation systems and processes is a major concern in an industry trying to move toward milder products and processes (eg, heat or fermentation processes targeted at salmonella may not be equally effective against *E. coli* O157:H7). These verocytotoxigenic *E. coli* provide a more severe food poisoning hazard than salmonella,[34] so that the reliability of processes used in manufacturing, at home, or in food service to ensure its absence has to be increased. In some cases the identification of food poisoning problems by epidemiological studies has prompted examination of the basis of safety rules. This has in some cases shown that the microbiological analytical methods used to assess the effects of a killing step may not have recovered sublethally damaged cells and therefore overestimated process effectiveness; prior exposure to sublethal stress can increase the resistance of *E. coli* and *L. monocytogenes* to heat[4] and acid.[89] In some cases, incorrect data of this kind has been translated into process requirements.

18.4.5 Microbial Destruction Techniques

Many products rely on heating (either pasteurization or sterilization) to kill microorganisms. Hence, heating is a major contributor to safety and stability, but may cause quality loss. This loss often results from the excessive heating required to achieve "coldest point temperatures." Hence, more uniform and accurate methods will be commercialized to minimize the heat input, eg, volumetric heating, using ohmic or microwave technology. The aim is to reduce energy costs and to achieve processes that are nearer to the minimum for specified product core temperatures and hence, lethalities.

Because inactivation is an essential part of preservation, an increasing range of technologies will be used to do this in future. Ultrahigh pressure (1,000–6,000 atm) has been used experimentally to decontaminate pork slurries and meat products; pressures in the range 3,000–6,000 atm for 10 minutes at 25°C kill vegetative cells (*E. coli*), but >6,000 atm is needed to inactivate bacterial spores (see Chapter 13).[127,208] Currently, the application of such methods is limited by variability in product characteristics, the cost, and low throughput of equipment and as the "unconventional" heating methods are currently "out-of-pack," their full exploitation relies on the availability of economically priced aseptic handling and packaging systems for slices and pieces.

There is international interest in the use of irradiation (either from cobalt or electron-beam accelerator sources)[71] to pasteurize or sterilize meat products.[216] However, before irradiation technologies can be used on any scale, there are two major hurdles to be overcome: consumer acceptance and the prevention of unacceptable product quality loss due to free radical reactions.

18.5.5 Stabilization Methods

Technological advances have concentrated on killing. There has been little application of innovative means of stabilization, ie, improvement of intrinsic preservation systems, such as the use of nisin and other natural antimicrobials in meat products.[29,39,153,206] This may be because of consumer and legislative conservatism[176] or doubts concerning their effectiveness. Pressure from consumers, or marketing departments, asks for healthier products with less fat, and therefore by inference, contain more water. This, coupled with a desire for low-salt products, gives lower salt-on-water concentrations and increases the risks of food poisoning as preservation systems become less robust.

There are many products below the generally accepted minimum 3% to 3.5% salt-on-water considered necessary for preventing the growth of psychrotrophic *C. botulinum* at chill temperatures (<12°C), and yet there is no marketplace evidence that they are hazardous. Consumer pressure for the removal or limitation of nitrite and salt continues and is reinforced by labeling legislation.[31,32] This pressure has led to a continuing search for alternatives such as lactate (2% to 2.5%) and increased reliance on chill storage.[100,171] The inhibition of pathogens in meat products relies increasingly on chill temperatures and less on the intrinsic (ie, pH, a_w, and salt) factors that are traditionally used. Improvements in manufacturing hygiene are reducing the important protective contribution of the spoilage flora and may increase the risks of unlimited growth of accidental, pathogenic, contaminants, such as *L. monocytogenes*. A major challenge to the industry is to conserve the low level of risk associated with the presence of a spoilage flora, while inhibiting its activity, so that long shelf lives at chill are achievable.

18.5.6 Selection/Handling of Raw Materials

The number of microbial pathogens and spoilage organisms present in raw materials can have a critical effect both on the microbiological challenge and the stability of a preservation system. There is little or no data on the contribution that the relatively low incidence of pathogens (eg, *C. botulinum* or *S. aureus*) in raw materials makes to product safety. Their assumed low incidence, coupled with improved hygiene and chilled storage, has been proposed by Skovgaard[212] as an alternative to the use of nitrite. However, even according to this author, the use of nitrite remains justified because of the difficulties of controlling hygiene and storage temperature. As raw materials are sourced on a global basis, established processes may be challenged with more, or different, microorganisms with different or increased heat or preservative resistances. Coverage of this is an essential part of hazard analysis and risk assessment.

Over the past 40 to 50 years, there has been an increased, but now reduced, use of natural spices in meat products. This reduction has occurred because of the availability of "extracts" of good sensory quality and an appreciation that the risks of spoilage are increased in mild products (such as luncheon meat), which become microbiologically unstable when challenged with high spore loads. Since 1986, input and residual levels of salt and nitrite in cured products have been reduced (from 300 to 150 ppm), but the geographically wide market for these products has meant that they are now subject to higher storage temperatures than envisaged in the original product design.[92] Therefore, it is not possible to conclude from their good safety record whether current usage is a well-controlled risk or whether there is only absence of evidence of failure.

Packaging materials, such as barrier films or cans, prevent microbiological recontamination and retain preservative atmospheres. Pressures to reduce packaging costs and eliminate "apparently" superfluous packaging material continually erodes the reliability that can be placed on this element of the preservation system. Loss of pack integrity by accidental damage may allow either contamination or a change to the preservation system, allowing spoilage or at worst toxin production. At present, clear guidelines on requirements for packaging functionality do not exist, and packaging should be treated as a key element in HACCP studies.

Increased preparation of processed meat products in food service outlets provides an opportunity for better control of distribution, storage, and preparation hygiene and cooking conditions. However, these tasks are often undertaken by poorly trained staff and within severe cost constraints. This has an adverse effect on product safety because of poor personal hygiene and excessive handling of foods leading to cross-contamination and inadequate temperature control. The common contaminants in shops selling raw and cooked meat are *E. coli* and *Enterococcus faecalis*.[23,221,222] On the positive side, many of the successful multiple retail stores and food service outlets in this sector of the market in Europe and North America have been in the vanguard of pushing high standards of food hygiene and safety, with very thorough employee training, control, and QA systems. Because of the costs of enforcement, and the recognition that quality and safety cannot be ensured by traditional inspection and product testing regimes, there are global moves toward industry self-regulation with the greater emphasis on companies basing product safety on process design and the control of processing by the application of HACCP and quality management systems (see Chapter 58).

19.1 INTRODUCTION

Raw salted meat products may be subdivided into three categories. In the manufacture of the first of these, whole muscle products like bacon or comminuted products such as Chinese-style raw sausage (mainly preserved by drying at temperatures around 50°C[102]), there is little, if any, enzymatic activity involved. In the second, various whole pieces of salted or cured meat undergo a ripening process involving tissue enzymes (ie, longer than just necessary for development of curing color and even distribution of salt), but the contribution of microorganisms to their sensory properties is small or absent. Such whole muscle products include aged "raw hams" as common in Continental Europe, as well as some other cuts of pork (eg, Italian "coppa") or from beef (eg, "pasterma," "Bündnerfleisch," or "bresaola"). The third category of fermented meats depends, by definition, on microbial activity. This applies, with few exceptions, to fermented sausages only. Hence, this chapter will focus on the microbiology of sausage fermentation and will only briefly mention possible roles of microorganisms in the manufacture of other meats. The other two categories of raw salted and/or cured meats are discussed in Chapter 18 of this volume.

19.2 TRADITIONAL TYPES OF FERMENTED MEATS AND THEIR MANUFACTURE

Because traditional ripening procedures require low to moderate temperatures, fermented meats are most widespread in regions with temperate climate.

Fermented sausages probably originated in the Mediterranean regions, whereas raw, salted, unground meats were more common in regions with colder, maritime climates. The few varieties of fermented meats indigenous to countries with hot climates include only products that can be dried rapidly and/or are eaten after cooking, eg, *nham*, a fermented sausage common in Thailand. A flow diagram of some typical processes used for the manufacture of fermented sausages is shown in Section 19.6.4 (Figure 19-2) and a list of the types of fermented sausages in Table 19-1. A more detailed list of the types of fermented meats is provided in several references.[18,102,196]

Fermented sausages are made from comminuted meat and fat, salt, curing agents, sugar, and spices. The mixture is filled into casings and subjected to a ripening process. Ripening comprises a *fermentation phase,* characterized by microbial activity, and, in most cases, an *ageing phase,* where the products are dried and develop typical aroma and flavor by complex reactions involving tissue or microbial enzymes or abiotic transformations. *Curing* means a treatment of the meat with curing agents (nitrite, mostly in combination with ascorbate, or nitrate), which brings about characteristic sensory changes (formation of curing color and curing aroma and flavor). These definitions will be used throughout this review.

About 750,000 tons of fermented sausages are produced annually within the European Union (EU).[55,113] Germany has the highest *per capita* consumption (about 4.5 kg per year), while in the United Kingdom (UK) and Ireland, consumption figures are very low, and there is little domestic production. In the United States (US), the annual *per capita* consumption is about 0.6 kg.[1]

There are various ways of classifying fermented sausages; one such classification is shown in Table 19-1. The most important criterion used is the water activity (a_w) of the product because this determines not only its market value but also its microbial stability. Traditional raw sausages with an a_w below 0.90 are, in this chapter, termed *dry sausages.* The a_w of *semi-dry* sausages is between 0.90 and 0.95, and they should be stored below 15°C. Spreadable sausages (a_w 0.94–0.96) lose little if any moisture during ripening, and their safety and shelf life are mainly ensured by pH. Another important factor that affects both the microbiological and the sensory properties of the sausage is the treatment of the sausage surface. Sausages that are not smoked develop a surface flora (molds, yeasts, Gram-positive cocci), which may be either washed off (as in some German-type air-dried sausages) or left on to add to the sensory properties of the product. Such mold-ripened sausages predominate in Italy, France, Spain, Switzerland, and Hungary, whereas in other countries including the US, most fermented sausages are smoked.

Sausages belonging to the different categories (Table 19-1) also differ with respect to their formulations and fermentation conditions. A general rule is

Table 19-1 Classification of Fermented Sausages

Category	*Ripening Times*	*Final Water Activity*	*Application of Smoke*	*Examples*
Dry, mold fermented	>4 weeks	<0.90	no	traditional Italian salami French "saucisson sec"
Dry, mold fermented	>4 weeks	<0.90	yes (during fermentation)	traditional Hungarian salami
Dry, no mold growth	>4 weeks	<0.90	yes or no	German "Dauerwurst"
Semi-dry, mold fermented	<4 weeks	0.90–0.95	no	various French and Spanish fermented sausages
Semi-dry, no mold growth	<4 weeks (usually 10–20 days)	0.90–0.95	yes (with exceptions)	most fermented sausages in Germany, The Netherlands, Scandinavia, US, etc
Undried, spreadable	<2 weeks	0.94–0.96	yes or no	German "Streichmettwurst"; Spanish "sobrasada"

Source: Reprinted from F.K. Lücke, Fermented Sausages, in *Microbiology of Fermented Foods,* 2nd ed., Vol. 2, B.J.B. Wood, ed., pp. 441–483, © 1998, Aspen Publishers, Inc.

that fully dry sausages with a long shelf life are fermented more slowly (ie, at lower temperatures) than the others, and care is taken to avoid excessive acid formation. Likewise, products intended to develop a surface flora are fermented more slowly than sausages to be smoked. The microbiological basis for this will be discussed in Section 19.4.1. Other parameters used to classify fermented sausages include the following:

1. the casing diameter
2. the degree of comminution of the ingredients
3. the animal species used for obtaining the raw material
4. the fat content and type of fatty tissue used
5. the use of special spices and seasonings
6. the types and proportions of other nonmeat ingredients.

19.2.1 Choice and Preparation of Raw Material

Fresh, raw, sausage mixture contains 50% to 70% lean meat, that is, mammalian (sometimes poultry) skeletal muscle tissue. Meat availability (and price), religious traditions, and eating habits determine the animal species. To avoid problems early in fermentation, meat should have a normal pH (5.5–5.8) and a low level of undesired microorganisms, eg, Enterobacteriaceae. For optimal color and consistency of the sausages, butchers prefer meat from old animals such as sows and avoid use of PSE (pale, soft, exudative) pork. The fatty tissue used should consist of fat with a high melting point. For dry sausages with a long shelf life, not more than 12% of the total fatty acid should be polyunsaturated[180]; otherwise, color and flavor defects and rancidity will develop early. Firm back fat from pigs fed a diet with limited levels of polyunsaturated fatty acids is most frequently used. In countries where religious tradition prohibits the consumption of pork, beef tallow or certain other fatty tissues from ruminants are used instead, eg, for Turkish *soudjouk*.[63]

The raw material is cut into appropriate pieces, which are subsequently chilled or frozen. By rapid freezing after slaughter and by avoiding long-term frozen storage, the peroxide content of fatty tissue is kept to a minimum.

19.2.2 Comminution

The raw material may be comminuted in cutters or grinders; the latter brings about a "shorter" (more crumbly) consistency required for various traditional products. It is important to keep the temperature close to the freezing point; otherwise, the efficiency of cutting will be reduced and fats may smear. It is common practice to add part of the raw material in the frozen state.

19.2.3 Additives

Addition of 2.5% to 3% (w/w) salt (sodium chloride) is most common. In conjunction with a moisture content of the mix of about 50% (as in common formulations), this will give an initial a_w of 0.955–0.965. Apart from its effect on the microflora and flavor, salt interacts with the myofibrillar structure and solubilizes proteins, which form a sticky film around meat particles. Nitrite is preferred as curing agent, for undried and semi-dry sausages with maximum input levels of about 150 mg $NaNO_2$ kg^{-1}. In many countries, nitrite may only be applied as a mixture containing about 0.5% sodium nitrite in NaCl. This effectively prevents overdosing of nitrite because such products would taste too salty. Sodium ascorbate (usually 300–500 mg kg^{-1}) is frequently added, together with nitrite, to accelerate the development of curing color and flavor. For dry sausages, manufacturers use nitrate (up to 300 mg KNO_3 kg^{-1}) or reduced levels of nitrite. Some fermented sausages are produced without any curing agents. This is possible if particle size is coarse, sausage diameter is small, and fermentation temperature is low.[192]

Carbohydrates are added to the mix to provide an energy source for lactic acid bacteria, but large amounts of milk powder or starchy products are sometimes used to modify flavor or simply used as a filler; the amount of fermentable carbohydrate needed depends on the initial pH and on the target pH after fermentation. Addition of 0.3% of glucose or another rapidly fermentable mono- or disaccharide will enable lactic acid bacteria to lower the pH by at least 0.5 units, which is sufficient for many products if meat of normal pH (≤ 5.8) is used.

Up to 0.5% glucono-δ-lactone (GdL) is sometimes added to the sausage mixture. It acts as an acidulant because it is hydrolyzed to gluconic acid within a few hours. It is fermented to lactic and acetic acid by various lactic acid bacteria. This may improve microbial safety but at the same time strongly interferes with other reactions required for development and maintenance of desired sensory properties (see below). Hence, GdL is used mainly in the manufacture of "fresh," undried, or semi-dry fermented sausages. The use of starter cultures for fermented sausages is discussed in Section 19.5 of this chapter.

Ground pepper is usually present in all types of fermented sausages at a concentration of 0.2% to 0.3%. Other spices commonly used include paprika, garlic, mace, pimento, and cardamon. Generally, air-dried sausages are more heavily spiced than smoked sausages. Apart from their effects on flavor, spices may also affect the microflora and the oxidative changes during ripening (see below).

19.2.4 Filling

Before filling into casings, oxygen should be excluded from the mixture (eg, by vacuum-filling devices), and the temperature of the mix should not exceed 2°C. Natural casings (made from intestines from slaughter animals) as well as casings made from modified collagen and/or cellulose are most frequently used. They must allow evaporation of water from the sausages and penetration of smoke, and they must follow the shrinkage of the sausage during drying. For undried products, synthetic casings are also used.

19.2.5 Fermentation

Most sausages are fermented at temperatures between 20° and 25°C for 2 to 4 days, although some American-style semi-dry sausages are fermented at temperatures up to 41°C.[9] The higher the temperature, the more rapid the fermentation, but the higher the risk of growth of mesophilic pathogens if acid formation is delayed or inhibited (see Sections 19.4.1 and 19.6.1). Moreover, a high rate and extent of acid formation interferes with the flavor and stability of the product during long-term storage. Hence, lower fermentation temperatures, in conjunction with low levels of fermentable carbohydrates, are applied in the manufacture of dry sausages with long shelf life and for mold-ripened sausages. Hungarian "winter salami"[80] or certain regional specialties in Germany are even fermented at temperatures as low as 8° to 12°C.

To avoid moisture condensation on the sausage surface, the sausages are first equilibrated to the ripening temperature at low relative humidity (RH) before entering the ripening chamber. During fermentation, the RH in the ripening chamber is maintained 5 to 10 units lower than the RH (water activity × 100) within the sausages (ie, about 85% to 90%), and the air velocity controlled at about 0.4 m/s.[178]

In the US, some sausages are heated at the end of the fermentation: regulations require heating to a core temperature of 58.3°C (137°F) if the presence of *Trichinella* cannot be excluded.[9]

19.2.6 Surface Treatment

If a "bloom" on the sausage surface is desired, sausages are dipped in suspension of appropriate starter molds (and/or yeasts) prior to fermentation. If the development of molds and yeasts on the sausage surface during drying or storage is to be prevented, the sausages are smoked, usually at the end of the fermentation period. Some regional specialties in Germany are *air dried,* ie, surface growth is prevented by control of relative humidity and repeated washings. In some countries, natamycin or sorbate dips are used to prevent the surface growth of yeasts and molds.

19.2.7 Ageing/Drying

Sausages are usually aged at 12° to 15°C. The climate in the ripening chamber should ensure a slow but steady drying of the sausages and prevent excessive mold growth on the surface while avoiding uneven drying of the product and the formation of a dry, hard outer layer on the sausages. Hence, the RH in the chamber is gradually lowered to about 75% to 80%, and air velocity is adjusted to about 0.1 m/s. Most fermented sausages are ripened in controlled environment chambers throughout the year. However, many small manufacturers do not have this rather expensive equipment available. Thus, they have to restrict production to suitable seasons or to undried products, or use various means to adjust the climate of the ripening room.

Most sliceable, semi-dry, fermented sausages (about 80% of the products on the German market) are dried to moisture contents of about 40%, which corresponds to a weight loss of about 18% and an a_w value of about 0.93. Dry sausages have 35% moisture or less, corresponding to a weight loss of 25% or more, and an a_w of < 0.90. Obviously, more water must be removed if the formulation includes less fat and more lean meat than normal.

19.3 MICROORGANISMS INVOLVED IN MEAT FERMENTATIONS, AND FACTORS AFFECTING THEM

19.3.1 Lactic Acid Bacteria in Sausage Fermentation

Unless the mixture is inoculated with large amounts of other lactic acid bacteria, lactic acid formation during sausage fermentation is due to the activity of "facultatively heterofermentative" *Lac-*

tobacillus spp., formerly designated as "streptobacteria." These bacteria ferment hexoses to lactate, and pentoses (many strains also gluconate) to lactate and acetate, and grow at 15°C. Early studies showed that the dominating strains could not be identified as validly described species and were therefore designated as atypical lactobacilli.[110] Compared with typical streptobacteria, these atypical lactobacilli (1) are capable of growth at lower temperature (most are able to grow at 4°C), (2) have a somewhat lower pH tolerance (no growth at pH 3.9), and (3) have a higher tendency toward pleomorphism (growth as coccoid cells on low-sugar media).[146,149] A taxonomic study by Kagermeier[86] assigned the atypical lactobacilli to *Lactobacillus sakei* and *Lactobacillus curvatus*. This was later confirmed using more advanced methods.[91] Later, *L. sakei* and *L. curvatus* were also found to dominate the lactic flora in various traditional Spanish,[77,159] Italian,[27] and Greek sausages.[157] Only in some sausage samples from countries with warm climates were mesophilic lactobacilli such as *Lactobacillus plantarum*[86] or *Lactobacillus alimentarius* present in large numbers; the latter species predominate in Turkish *soudjouk*.[65] The data indicate that the reservoirs of psychrotrophic lactobacilli are cold rooms or, even more likely, cutting rooms that are kept at 12°C or below (in accordance with meat hygiene regulations within the European Union), and in which the meat is easily contaminated from reservoirs of psychrotrophic bacteria. It is noteworthy that the species of lactic acid bacteria involved in sausage fermentation are also involved in the spoilage of vacuum packed meat and pasteurized meat products. This also indicates a common reservoir of the strains, namely, the cutting room.

Streptococcus, *Enterococcus*, *Lactococcus*, and *Pediococcus* species cannot compete well with the psychrotrophic lactobacilli at fermentation temperatures commonly employed in Europe and, therefore, comprise only a minor part of the population.[86,146] However, some pediococci have proved to be good starters for various types of sausages (see Section 19.5). Strains producing CO_2 from glucose anaerobi-

[a] +(–), positive with exceptions; –(+), negative with exceptions; V, variable (strain dependent).

[b] *L. pentosus* is similar to *L. plantarum* but capable of fermenting D-xylose.

[c] Strains forming L-lactate only have been formerly classified as *L. bavaricus*.

[d] All strains ferment glucose and ribose.

cally (*Leuconostoc, Weissella,* and heterofermentative lactobacilli) made up less than 10% of the population. They are undesirable in fermented sausages because they form gas from sugars, and some strains produce slime from sucrose.

Some properties of the species of lactic acid bacteria predominant in fermented sausages and/or available as starters for these products are shown in Table 19-2. All species listed ferment glucose and ribose and produce DL-lactate, except some *L. sakei* strains formerly named *Lactobacillus bavaricus. L. plantarum* possesses both D- and L-lactate dehydrogenases, while *L. sakei* and *L. curvatus* form L-lactate dehydrogenase and racemase.[87] The sugar fermentation pattern and its genetic basis is not very stable in meat lactobacilli, and there is much variation within one species.[45,91,169] Hence, it is important to use the right combination of starter and fermentable sugar.

In the range of relevance to meats, growth of the species listed in Table 19-2 is not affected by pH. Likewise, oxygen is not inhibitory to growth, but may influence the balance of fermentation products by enabling the organisms to oxidize pyruvate to acetate and CO_2. Also, strains that possess flavin-dependent oxidases and little or no peroxide destroying activity accumulate hydrogen peroxide which may cause color and flavor defects (see Section 19.7). Sodium chloride and sodium nitrite, if present at levels equivalent to those in sausage mixtures, lower the rate of acid formation only slightly. The minimum a_w for growth depends somewhat on the strain. In culture media, some strains are only inhibited in the presence of about 12% sodium chloride (approximate a_w 0.91), and acid production in fermented sausages also ceases once the a_w is below 0.91.[98,108] The minimum temperature permitting growth varies between the species; the pediococci as well as *L. plantarum* and *L. pentosus* do not grow at 4°C. This is the main reason why these species are rarely encountered in sausages fermented without starter cultures.

19.3.2 Catalase-positive Cocci

As will be explained later, nonpathogenic, catalase-positive cocci play an important role in forming and stabilizing the desired sensory properties of fermented sausages. Most strains isolated from sausages produced in France,[39] Germany,[54,150] Italy,[27] Spain,[168] and Greece[158] were found to be *Staphylococcus* species. Differentiation into species revealed that *S. xylosus* and *S. saprophyticus* are widespread both in German and French dry sausage as well as in sausages on the British market[39,54,167]; *S. xylosus* dominates in most products manufactured without starter, such as Italian salami.[27] In samples from Germany, *S. carnosus* (originally identified as *S. simulans*) and *Micrococcus varians* are also found frequently.[54] These strains may originate from the starter cultures in use in Germany in the late 1970s.

Staphylococci and micrococci (formerly included in one family, *Micrococcaceae,* but now shown to be only distantly related phylogenetically) have in common that they grow at low water activity (some strains down to a_w 0.86 under otherwise optimal conditions), but are inhibited by low pH and low temperature. Staphylococci are less dependent on oxygen than are micrococci, and this is the main reason why they are found in higher numbers in fermented sausages than the latter. However, growth of all catalase-positive cocci in fermented sausages is restricted to regions close to the surface. High numbers are reached if the products are fermented slowly, not smoked, and if the surface pH rises because of mold growth. In rapidly fermented, smoked sausages, there is hardly any growth of these bacteria.

19.3.3 Yeasts and Molds

The mold flora developing on fermented meats consists of *Penicillium* species, sometimes accompanied by *Scopulariopsis* spp.[84] *Penicillium verrucosum, Penicillium chrysogenum, Penicillium frequentans, Penicillium nalgiovense,* and *Penicillium variabile* are most frequently isolated.[79,105] Aspergilli are rarely found because of their higher temperature optimum. Of the yeasts, *Debaryomyces hansenii* and its imperfect form, *Candida famata,* are best adapted to this environment characterized by low availability of sugars and high levels of salt. Growth of yeasts usually precedes the growth of molds.[5]

19.4 MICROBIOLOGICAL, CHEMICAL, AND PHYSICAL CHANGES DURING MEAT FERMENTATIONS

19.4.1 Sausage Fermentation and Ageing

Day 1: Reactions Involving Oxygen, Nitrite, and/or Gram-Negative Bacteria

After comminution of the meat and filling into casings, oxygen in the sausage mixture is consumed by respiratory enzymes. These enzymes are inhibited by nitrite, which accordingly delays this process. Without nitrite, the oxygen partial pressure approaches zero after about 6 hours whereas up to 24 hours are required after addition of *ca.* 140 mg sodium nitrite kg^{-1}.[152]

If no nitrite is added, the red color of fresh meat is only gradually lost; low partial pressure of oxygen as well as salt accelerate the oxidation of myoglobin to brownish metmyoglobin. The formation of curing color is outlined in Figure 19-1. If sausages have been prepared with added nitrite, they turn brownish rapidly because the oxygenated (red) myoglobin reacts with nitrous acid to give brown metmyoglobin and nitrate. Metmyoglobin then reacts with nitrous acid and/or nitric oxide (from acid-catalyzed disproportionation of nitrous acid) and indigenous and/or exogenous reductants (eg, ascorbate) to give red nitric oxide myoglobin (NOMb), the NO group occupying the sixth ligand position of the heme. The rate of NOMb formation increases with falling pH and is therefore accelerated by the activity of the lactic acid bacteria in fermented sausage. Hence, the formation of cured meat color is normally not complete within the first day.

Aerobic Gram-negative rods (in particular, the psychrotrophs *Pseudomonas fragi, Pseudomonas fluorescens,* and *Pseudomonas lundensis)* make up the majority of the microbial population on aerobically chill-stored fresh meat.[95] Psychrotrophic Enterobacteriaceae are also present while Gram-positive organisms, including lactic acid bacteria, usually occur only in small numbers except if trimmings from meat (particularly beef) are used that have been stored in vacuum packs. Growth of pseudomonads and other aerobic Gram-negative bacteria is readily inhibited at a_w values of about 0.96 (which is the normal a_w of the sausage mix), by lack of oxygen, and by nitrite. Likewise, the degradation of amino acids that would cause the typical off-odors of spoiled meat is largely suppressed. The competitiveness of the Enterobacteriaceae is reduced but not abolished at low oxygen tension, low pH, and in the presence of salt. Their activity within the first 24 hours after filling is largely inhibited by added nitrite. Although this may be desirable in terms of microbiological safety, there is some evidence[192] that nitrite also suppresses the formation of aroma precursors by Gram-negative bacteria early in fermentation. This, along with differences in oxygen content, may be the reason why, empirically, many sausage makers use nitrate or reduced input levels of nitrite for long-ripened dry sausages.

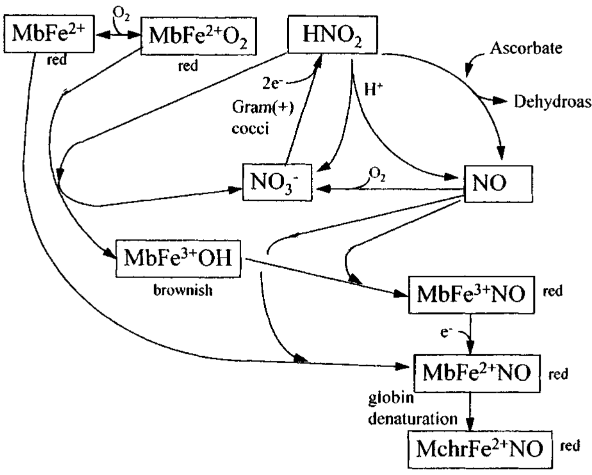

Figure 19-1 Schematic Representation of the Reactions Leading to Cured Meat Color Formation during Sausage Fermentation. $MbFe^{2+}$, myoglobin; $MbFe^{2+}O_2$, oxygenated myoglobin; $MbFe^{3+}OH$, metmyoglobin; $MbFe^{3+}NO$, nitric oxide metmyoglobin; $MbFe^{2+}NO$, nitric oxide myoglobin; $MchrFe^{2+}NO$, nitric oxide myochromogen.

The Fermentation Period Sensu Stricto

The fermentation period *sensu stricto* is characterized by the acid production by lactic acid bacteria, and by completion of cured color formation. The time course of acid formation (apparent lag phase, maximum rate, final pH) is determined by intrinsic (formulation) and extrinsic factors (mainly temperature) in the following ways:

1. A high initial pH of the mixture will have little if any effect on lag and rate but lead to higher final pH values. However, it favors growth of acid-sensitive undesired organisms and may make the process unsafe (see above).
2. Addition of high levels of well-adapted lactic acid bacteria will shorten the apparent lag phase but not necessarily increase rate and extent of acid formation.
3. At low initial a_w (< 0.955), acid formation will be delayed, and rate and amount reduced.
4. At input levels of about 150 mg kg^{-1}, sodium nitrite may somewhat decrease the rate of acid formation[141]; however, its effect on Gram-negative bacteria and listeriae is much stronger than its effect on the lactic acid bacteria.
5. The choice of added sugar affects the length of the lag phase and the rate of acid formation[92,142]; glucose supports fastest and most complete acidification. "Slow" sugars (such as lactose) also tend to give higher final pH values because progressive drying of the product in later stages of the fermentation interferes with acid formation.[108]
6. With increasing levels of rapidly fermentable sugars, more acid will be formed and lower pH values attained.

7. Addition of natural spices may increase the rate of acid formation.[128,187] This is due to their manganese content[195] and the fact that some essential enzymes of lactic acid bacteria including a key enzyme of glycolysis, pyruvate kinase, require manganese.[144]
8. At high fermentation temperatures, the lag before acid production commences tends to be shortened and the rate increased. However, high temperatures may favor mesophilic pathogens and thus, like high initial pH, jeopardize product safety unless appropriate combinations of sugars and starters are used.

If acid production starts too late or proceeds too slowly, pathogens like salmonellae and *Staphylococcus aureus* may grow (see Section 19.6). On the other hand, the activity of the acid-sensitive nonpathogenic staphylococci and micrococci is important, particularly in the manufacture of dry sausage with a long shelf life. To restrict acid formation, such products are made with less sugars and fermented at lower temperatures (see above). Moreover, excessive amounts of acid are undesirable in many fermented sausages and are one of the important causes of product spoilage (see Section 19.7).

The main product of carbohydrate fermentation in ripening sausages is DL-lactic acid, with only small variations between the two enantiomers.[86,108] Most lactic acid bacteria, particularly the "facultatively heterofermentative" lactobacilli predominating in sausage fermentation, also form some acetic acid from ribose or, if alternative electron acceptors (such as oxygen) are available, from pyruvate and/or lactate.[87] After fermentation, average molar ratios of lactic acid to acetic acid of about 7 were found both in smoked[38,40] and unsmoked salami.[61] This is similar to the ratio found in liquid cultures of meat lactobacilli.[135,147] If they excluded oxygen from the sausages by vacuum filling, Deketelaere et al.[38] could recover 88% to 103% of carbohydrate fermented as lactic and acetic acid. Incomplete recovery of carbon indicated loss of carbon dioxide and other volatile compounds from the sausages, which is particularly great in products of small diameter.[41] Small amounts of acetoin, diacetyl, and/or 2,3-butanediol may also be formed by lactic acid bacteria both in culture media and in sausages, and appear to contribute to the "cheesy" component of the sausage aroma.[12,35]

Most semi-dry sausages in Belgium and Germany have pH values of 4.8–5.0 after fermentation, which corresponds to a concentration of approximately 25 g lactic acid kg^{-1} dry weight.[38,108] Some semi-dry fermented sausages produced in the US are even more acidic, whereas in the manufacture of undried sausages the extent of pH decrease is limited in order to keep them spreadable. During the traditional manufacture of Italian and Hungarian salami, the pH remains above 5.3 throughout ripening.[80]

Lowering the pH of the sausages to 5.3 or below inhibits bacteria other than lactobacilli and pediococci, and provides the "sour" component of the sausage aroma. In addition, this pH is close to the isoelectric point of many muscle proteins, and water-binding capacity becomes minimal. Accordingly, the firmness of the sausages rapidly increases, and moisture may be removed easily, but on the other hand it becomes more difficult to maintain the "spreadable" consistency of undried sausages. Lastly, the disproportionation of nitrite and, correspondingly, the formation of cured color is accelerated at low pH.

To be effective as a curing agent, nitrate added as such or formed from nitrite by abiotic reactions (see Section 19.4.1), must be reduced to nitrite by microorganisms. Some strains of *L. plantarum* and *L. pentosus* reduce nitrate *in vitro*, but only when cultivated in media with high pH and little sugar[31,86]; rates are insufficient for proper color and flavor development in meats,[69] and the acid-sensitive catalase-positive cocci are the main agents of nitrate reduction. Therefore, the pH should be above 5.4 until sufficient nitrate is reduced.[130]

Sufficient activity of catalase-positive cocci is not only required for nitrate reduction, but also to form and to stabilize aroma and flavor in the manufacture of sausages with a long shelf life. It is common experience that these sausages should be fermented slowly, and that GdL is unsuitable as an acidulant: this compound is fermented to lactic and acetic acids, and catalase-positive cocci are severely inhibited. Accordingly, GdL sausages are very prone to rancidity and color defects and have only a short shelf life.

Whether added as such or formed by microbial nitrate reduction, nitrite is reduced further by many microorganisms present in the sausage, including the nitrate-reducing microflora as well as several strains of lactic acid bacteria.[25,31,193] This reaction is important to eliminate any nitrite not used for curing reactions. It is sometimes claimed that microbial nitrite reduction is necessary for NOMb formation. However, nitric oxide is not an intermediate of nitrite reduction to ammonia by heme-containing nitrite reductases present in many bacteria including *Staphylococcus carnosus*,[71] which is frequently used as starter culture for fermented sausages. Moreover, sausages fermented with pediococci alone (eg, US-type summer sausages) develop good cured color even though the pediococci do not have nitrite reductases that form nitric oxide.[69] The conflicting results of Garcia et al.,[57] who did not observe curing color formation in aseptically prepared sausage with 100 mg $NaNO_2$ added per kg unless a *Micrococcus* strain had been added, could be due to a massive transformation of added nitrite into nitrate under their processing conditions.

Smoking

Smoke contains volatile antimicrobial compounds such as short-chain fatty acids and aldehydes, and after smoking growth of microorganisms on the sausage surface is inhibited for some time. The products are smoked after the fermentation period although some smoke may be applied earlier if care is taken not to inhibit the fermentation. Phenolic compounds in smoke also act as antioxidants and convey the typical aroma and flavor of smoked products. In the US, fermented sausages made from noncertified pork are usually hot smoked, ie, heated to 58.3°C internal temperature during smoking in order to inactivate trichinellae.

Ageing

Most fermented sausages undergo an ageing procedure characterized by drying (see Section 19.2) and formation of desirable aroma and flavor. Cured color is stabilized because the protein moiety of NOMb is partially denatured and the resulting nitric oxide myochromogen binds nitric oxide more tightly. In unsmoked sausages, a desired "surface bloom" of molds, usually associated with yeasts, develops; otherwise, there is little growth of microorganisms during sausage ageing.

Prior to ageing, the aroma and flavor of fermented sausages are dominated by metabolites from carbohydrates: the products are more or less "sour" and "cheesy," and, if acid formation is restricted, they retain more of the aroma and flavor of fresh meat. At a given pH, a high proportion of acetic acid gives the product a less "pure" and more "sour" flavor.

Most compounds affecting aroma and flavor of an aged sausage originate from lipid and protein degradation. The longer the ripening time, and the higher the activity of microorganisms other than lactic acid bacteria during and after the fermentation period, the higher the levels of volatile compounds with low sensory thresholds that are found.[99,100] Abiotic reactions, tissue enzymes, and microbial enzymes contribute to their formation. A review on the flavor chemistry of fermented sausages has been published recently.[35]

Lipids are precursors of many unbranched aldehydes, 2-alkanones, and short-chain unbranched fatty acids. The first reaction step toward these compounds is lipid peroxidation. This reaction is catalyzed by non-heme iron and partially inhibited by nitrous acid, which binds to this "pro-oxidant." This results in lower levels of volatile carbonyls and a shift in their composition (cured aroma).[64] Attempts to replace nitrite by other antioxidants have had little success[116,191] but certain spices have antioxidative constituents.[67]

The sausage microflora, in particular staphylococci and micrococci, may further modify the carbonyl compounds generated by lipid autoxidation[171] and form compounds, which add to the desired aroma of the sausages. For example, Stahnke[175] reported a positive correlation between the levels of 2-alkanones, salami odor, and numbers of *Staphylococcus xylosus.*

Lipids are also hydrolyzed to free long-chain fatty acids during sausage ripening. These fatty acids have little effect on aroma and, at higher levels, detrimental effects on flavor. However, like lipids, unsaturated fatty acids are further degraded to carbonyls and short-chain fatty acids with peroxides as intermediates.[21] There is some controversy in the literature as to the relative role of tissue and microbial enzymes in lipolysis. Very few strains of lactic acid bacteria from meats[3] but many catalase-positive cocci[29,137] as well as many yeasts and molds from fermented sausages[26,103,104] were found to hydrolyze pork fat (lard) *in vitro.* Cantoni et al.[19] suggested that catalase-positive cocci are the main lipolytic agents during sausage fermentation. The specificity of lipolysis observed by Demeyer et al.[42] supported this finding. Stahnke[174] found elevated amounts of long-chain fatty acids in sausages fermented with a lipolytic *Staphylococcus xylosus* but this had no impact on flavor. On the other hand, lipolysis begins very early in fermentation,[44] and appears to occur even in the absence of catalase-positive cocci or other bacteria.[57] This indicates that tissue lipases rather than microbial lipases are the main agents of lipolysis early in fermentation.

During sausage ripening, a significant portion of the protein is hydrolyzed.[131] Nonprotein nitrogen increases by about 20% in smoked sausages.[43] Experiments by Verplaetse et al.[189] and others[41] indicate that tissue proteases (in particular, cathepsin D) are the main agents of proteolysis early in fermentation.

Cathepsin D is activated at pH values of about 5.0 and produces peptides that are then further metabolized by lactobacilli[126,127] and catalase-positive cocci. During air drying of sausages, molds growing on the surface also hydrolyze proteins and catabolize amino acids. This is easily recognized by the ammonia smell of ripening rooms and the resulting products. The intensity of flavor of such sausages was found to be proportional to the degree of proteolysis.[60]

Amino acids not assimilated by the microflora are further metabolized, both in smoked[43] and air-dried sausages. Most branched-chain volatiles probably originate from amino acids.[66] The ammonia and the amines formed, in conjunction with lactate oxidation at the surface and an increase in osmolarity, account for the rise of the pH that is observed during drying of sausages. This rise is particularly marked in unsmoked products where molds and yeasts colonize the surface and degrade not only proteins but also lactic acid. These products obviously taste quite different to the smoked "sour" sausages. A proper selected mold culture on the sausage surface also keeps oxygen away from the sausage, provides a "microclimate" that favors the correct drying of the product, and prevents the establishment of undesired molds.

Yeasts also affect color and flavor when added to the sausage mixture.[32,58,125,156] These effects may be due to their oxygen-scavenging activity, but possibly also may be due to other by-products of fermentation and/or to their action on lipids; particularly high amounts of carbonyls (especially long-chain aldehydes) have been found in yeast-ripened sausages.[100]

Amino acids and their nitrogen-containing degradation products may contribute to the taste of the sausage but less to the aroma, because few if any nitrogen-containing volatiles have been found in fermented sausages.[13,35] Various esters (mainly ethyl esters) are found among the volatiles of fermented sausages,[35] and to contribute to salami odor. The data of Stahnke[175] suggest staphylococci (eg, *S. xylosus*) as main agents.

19.5 STARTER CULTURES

19.5.1 History

Use of starter cultures for meat fermentation has been reviewed recently.[68,83] The roles of, and benefits from, different species of microorganisms available as starter cultures for sausage fermentation have been outlined in the previous paragraphs.

The interest in starter cultures arose parallel to the trend toward industrial production, short ripening times, and standardization of product properties. In the US, the key role of lactobacilli in sausage fermentation was recognized early [Jensen and Paddock, US patent no. 2,225,783, Dec. 1940]; however, early attempts to introduce *Lactobacillus* strains as starters failed because suitable strains did not readily survive lyophilization. *Pediococcus cerevisiae*, now classified as *Pediococcus acidilactici*, proved suitable for the manufacture of products like summer sausage or thüringer cervelat,[36,37] which are fermented at temperatures above 30°C. *P. acidilactici* can be easily stored in a lyophilized or frozen form and is still widely used as starter in the US. In Europe, sausage makers were faced with the problem that a rapid lactic acid fermentation suppressed the organisms containing catalase and nitrate reductase, with consequent faults in color and flavor. Hence, they regarded lactobacilli as spoilage rather than beneficial agents, and a *Micrococcus* strain was first introduced as a starter culture by Niinivaara.[130] This strain (M 53) was selected because it rapidly reduced nitrate, improved color and flavor, and inhibited undesired microorganisms.[140] Further work by Niinivaara's group in Finland[136] eventually led to the development of starters containing a combination of a "Micrococcus" (later identified as *Staphylococcus carnosus*[165]) with *Lactobacillus plantarum*, the latter strain being superior to *Pediococcus cerevisiae* in sausage fermentation at 20° to 22°C. Early attempts to improve sausage manufacture and quality by using "atypical lactobacilli" (for example, *L. sakei*, and *L. curvatus*) as starters were of limited success,[148] even though these strains dominate in virtually all traditional European-style sausages. However, strains suitable for sausage ripening were selected later and became commercially available.

19.5.2 Selection Criteria for Starter Cultures

Selection criteria for starter cultures for meats have been summarized by Jessen[83] and Knauf.[93] Under the conditions (eg, pH, a_w, temperature, concentrations of curing agents) prevailing during fermentation, they must perform their desired activities at appropriate rates and after a lag as short as possible. They must be suitable for large-scale cultivation and preservation by freezing and lyophilization. They must not be pathogenic and must neither form toxins nor antibiotics. Moreover, they should not form compounds conveying unpleasant sensory properties. During *in vitro* screening of lactic acid bacteria for suitability as starter cultures, strains forming CO_2 from hexoses, amines from amino acids, volatile sulfur compounds from sulfur-containing amino acids, slime, or large amounts of hydrogen peroxide are rejected. Laboratory and pilot-plant sausage fermentation tests are then done to select strains of lactic acid bacteria, or any other microbial group, that form pleasant aromas and flavor notes.

Technological criteria for selection of mold starters include competitiveness on the sausage surface (ie, in the presence of salt, curing agents, and lactic acid, and at temperatures of about 15°C), adhesiveness to casings, white or slightly yellowish color (ie, no formation of conidia during sausage drying), and formation of appropriate aroma and flavor. Strains fulfilling these requirements belong to the species *Penicillium nalgiovense* (biotypes 2, 3, 6) and *Penicillium chrysogenum.* Any potential mold starter must be carefully tested by chemical and biological assays for the absence of mycotoxins and antibiotics, bearing in mind that most strains of *P. nalgiovense* and *P. chrysogenum* form the mycotoxin cyclopiazonic acid[49] and many strains form the antibiotic penicillin.[6] Mintzlaff and Leistner[124] selected a strain of *P. nalgiovense* as a starter culture, and later investigations[53,79] showed that other strains of *P. nalgiovense* and *P. chrysogenum* are likewise beneficial to the appearance and flavor of air-dried sausages.

19.5.3 Choice and Application of Starters

The necessity and choice of starters depends on the type of fermented sausage to be produced. Use of lactic acid bacteria is important for the safe production of rapidly fermented semi-dry sausages, whereas at low ripening temperatures (in particular, below 18°C), the effect of starters is small, and excellent fermented sausages have been (and still are) manufactured without addition of starter cultures or reinoculation of finished sausages. Species of which strains are commercially available as starters have been listed in Table 19-2. *P. acidilactici* is only effective at fermentation temperatures above 25°C as used in the manufacture of US-type summer sausage; in the temperature range between 20° and 25°C, its rate of acid formation is too slow to be of much benefit, and cultures containing *L. sakei* strains tend to have the fastest rates and to be most competitive. Acidification rates by *P. pentosaceus*[74,85,163] and *L. curvatus*[98] depend greatly on the culture used, and may be equal to or higher than those of *L. plantarum* and *L. pentosus. P. pentosaceus* is often stated to form a "milder" aroma.[83] *P. pentosaceus* and *L. plantarum* are not very effective in suppressing large numbers of lactobacilli present in the raw material.[33,119] However, excessive lag phases after inoculation of the mix may abolish the advantages of using a culture with a high acidification rate. With this in mind, a "starter sausage" containing a strain of *L. curvatus* is produced centrally and distributed frozen, mainly in The Netherlands.[96] Under these conditions, care must be taken to ascertain sufficient activity of desired acid-sensitive bacteria. At any rate, it is essential to follow the instructions of the starter manufacturer, and not arbitrarily combine different starters, sugars, and fermentation temperatures.

As pointed out earlier, use of starters containing catalase-positive cocci is particularly useful for products prepared with nitrate, and for products to have a long shelf life. The addition of sufficiently high levels (10^6–10^7 g^{-1}) of nonpathogenic *Staphylococcus* or *Micrococcus* (*Kocuria*) spp. largely eliminates the need to allow these bacteria to multiply in the product by keeping the pH in the permissive range (>5.3). Strains of *S. carnosus, S. xylosus,* and *Micrococcus* (*Kocuria*) *varians* are commercially available. Because of its requirement for oxygen, *M. varians* is less competitive in sausages than are the staphylococci, but it has a higher activity of nitrate reductase at 15°C.[93] Whether or not a yeast (*Debaryomyces hansenii/Candida famata*) or a culture containing *Streptomyces griseus*[46] is useful depends very much on the aroma note desired. Mold starters are generally recommended for the manufacture of mold-ripened products.

Starter cultures are distributed frozen or freeze dried on suitable carriers. Frozen cultures generally have a shorter lag phase although this is somewhat less critical than in dairy fermentations that are to be finished after hours rather than days. An even distribution of the culture in the mix is important to ensure homogenous fermentation.[89] Some sausage manufacturers resuscitate lyophilized cultures for several hours before use, but none of them propagate commercial starters *in vitro* any further.

Most commercial preparations contain a combination of lactic acid bacteria with nonpathogenic staphylococci or micrococci. For slower fermentations and/or products with a long shelf life, preparations containing less or even no lactic acid bacteria are also used. Defined cultures have shown to be useful for the manufacture of a wide spectrum of traditional sausage varieties and have replaced, to a large extent, so-called "back-slopping" methods where a fermented sausage from the previous batch is used to inoculate the following batch. The disadvantage of this method is that desired catalase-positive cocci will tend to become "diluted out," and strains with undesirable metabolic properties may be selected.

Lücke et al.[113] provided information on the use of starter cultures for sausage fermentation in various European countries. The data (summarized in Table

19-3) reflect the differences between the countries with respect to the predominant product types and the level of standardization and automation achieved by the processors.

Lactic acid bacteria and staphylococci are also available as starter cultures for the ripening of raw hams. If injected into the meat, these cultures are useful if cuts with high pH (6.0–6.2) are to be processed into raw hams.[82] In traditional manufacture, however, there is little benefit from these cultures because temperatures and a_w values on the surface of meat are too low. Certain strains of *Halomonas* or *Vibrio* may be useful for the curing of hams in nitrate-containing brines,[121] but the small market, problems with culture preservation, and the costs of safety testing appear to have prevented their marketing so far. For similar reasons, no Gram-negative bacteria are available in starter cultures for sausage fermentation, even though Petäjä[139] was able to improve the aroma of fermented sausages by combining an *Aeromonas* strain with *Lactobacillus plantarum.*

19.6 APPLICATION OF HACCP TO THE PRODUCTION OF FERMENTED MEAT PRODUCTS

It is generally agreed that the microbial safety of food can be most effectively achieved if the manufacturer follows the principles of the Hazard Analysis Critical Control Point (HACCP) concept as outlined in Chapter 58. Accordingly, there is legal pressure to introduce HACCP. Unfortunately, there is a lot of confusion resulting from inconsistent use of terms, mistranslations, and misconceptions. In agreement with the Guidelines of the Codex Alimentarius Commission, this section defines only those steps in production as "critical control points" (CCP) where loss of control may increase the health risk for the consumer, and where monitoring is feasible. HACCP complements "good hygienic practice," ie, general hygiene rules for facilities, equipment, and staff as detailed in various laws, directives, and codes of practice; for example, in the EU directives or Codex Alimentarius Commission recommendations on meat hygiene. For references and detail descriptions of Good Hygienic Practice and HACCP, see Chapter 58.

Only microbial hazards are dealt with in this section, although chemical hazards (eg, drug residues in the meat) or physical hazards (eg, splinters of bones or metals in the meat) are also relevant. However, chemical hazards (except for polycyclic hydrocarbons from smoke, and nitrite and/or nitrosamines) must be kept under control by good animal husbandry and slaughterhouse practices; the physical hazards are not specific to fermented meats.

19.6.1 Survival and Growth of Foodborne Pathogenic Bacteria in Meat Fermentations

Salmonella *and* Yersinia enterocolitica

During properly controlled sausage fermentation, the Enterobacteriaceae count remains constant and

Table 19-3 Use of Bacterial Starter Cultures for Sausage Fermentation in Various Countries

	% of Production		
Country	*Mold Fermented*	*Industrial*	*Use of Bacterial Starters*
Denmark, Sweden, Norway, Finland, Netherlands	0	>95	lactic acid bacteria for virtually all products; Gram (+) cocci less frequently
Germany, Belgium	10	85	for *ca.* 80% of production (less for slow-fermenting traditional types and for "fresh," not aged products)
Austria	30	80	as for Germany
Switzerland	60	50	as for Germany
France	95	90	for ca. 50% (less for slow-fermenting traditional types)
Italy	80	60	for 20% to 30% of production
Spain	65	70	for 20% to 30% of production ("backslopping" still common)
Greece, Portugal	<20	>80	for <30% of production ("backslopping" still common)

then decreases. Factors that may favor the growth of Enterobacteriaceae during sausage fermentation, and thereby increase the risk of salmonellosis, include a high initial water activity; a high initial pH value; a low concentration of fermentable carbohydrates; low numbers of lactobacilli in the fresh sausage mixture; the use of nitrate or of very low levels of nitrite as the curing agent[73,170]; and high ripening temperatures.

In Germany, some outbreaks of salmonellosis have been traced to the consumption of "Frische Mettwurst" (fresh, spreadable sausages). To retain their "fresh" consistency and "meaty" taste, such sausages have high water activity, are often manufactured with little, or no, sugar or acidulant (GdL), and are subjected only to a fermentation at 20° to 25°C for 1 or 2 days. This is sufficient for cured color formation but does not always suppress the growth of Enterobacteriaceae. In such sausages, increasing the amount of added salt to at least 2.5% (w/w) and addition of appropriate lactic acid bacteria, together with some fermentable carbohydrate or small amounts of GdL, is most effective for the control of Enterobacteriaceae including salmonellae.[166]

During drying, Enterobacteriaceae including salmonellae and yersiniae are slowly inactivated. Reported rates for *Salmonella* destruction during sausage ripening differ markedly from less than 1 log[160,176] to 3–4 log in smoked dry products with low final pH.[172] Likewise, inactivation rates for *Yersinia enterocolitica* during sausage fermentation vary between zero and 5 log, mainly depending on rate and extent of acid formation and drying.[8,90] For European-style smoked products, a reduction of numbers of salmonellae by 1 or 2 logs[75] is in agreement with the observation that salmonellae occur much less frequently in dry sausages than in ground meat or fresh, only slightly fermented raw sausages.[15,166] Nevertheless, outbreaks of salmonellosis from semi-dry or dry sausages have also been reported. In one of them,[106] a processor had combined very low input of nitrite (as common in Italian-type sausage formulations) with a fermentation temperature above 25°C (as common for US-style summer sausages). Another outbreak affected consumers (mainly children) who had eaten dry salami sticks.[34] Apparently, the salmonellae present in the raw material did not multiply during fermentation but survived the drying process, and the infective dose was small because the salami sticks were eaten as snacks by infants and young children.

Enterohemorrhagic Strains of Escherichia coli (EHEC)

Two severe outbreaks of hemorrhagic colitis from fermented sausages occurred in western states of the US and in Australia.[7] The infective dose of the causative agent, enterohemorrhagic strains of *Escherichia coli* (EHEC), is generally low, and multiplication during sausage fermentation is not required to cause disease. Moreover, inactivation during sausage ripening may be slow: reductions by 1 to 5 logs were observed, mainly depending on pH, water activity, ageing time, and temperature,[51,62,94,177] and possibly also as a result of acid adaptation of the cells.[107] Fortunately, the prevalence of EHECs in meat appears to be low and restricted to beef and lamb.[16] However, as long as no effective control measures on the farm or at meat inspection level exists, it is advisable not to include beef- or lamb-containing raw sausages with short ripening times into the diet of small children (the main risk group for hemorrhagic colitis and its life-threatening sequela disease, acute renal failure).

Staphylococcus aureus

Staphylococcus aureus is frequently found in raw meat and fermented sausages, but generally only at low levels. Only if allowed to grow to cell densities above 10^7 g^{-1}, does it form levels of enterotoxins sufficient to cause illness. Growth of this organism has been studied during ripening of various types of raw sausages. The bacterium is little affected by salt and nitrite, but it is a poor competitor under anaerobic conditions, at low pH values and low temperatures (see Chapter 47). It may grow at high fermentation temperatures during the lag phase of the development of lactic acid bacteria and may reach high numbers in the outer layers of the sausages.[10] Niskanen and Nurmi[132] and Metaxopoulos et al.[122,123] showed that the initial pH value and the initial activity of the lactic acid bacteria are critical for the control of *S. aureus*. If sausages are fermented at a temperature no higher than 25°C for 2 to 3 days, and the initial count of *S. aureus* is below 10^4 g^{-1}, the risk of enterotoxin formation is low,[75] even if the sausages are not smoked.[76,122,123] However, fermentation temperatures up to 43°C are common in the manufacture of smoked, semi-dry sausages in the US. Under such conditions, only a rapid pH drop in the sausages early in fermentation ensures inhibition of *S. aureus*.[143] Consequently, the American Meat Institute, in 1982, specified the maximum time t_{max} (hours) allowed in "good manufacturing practice for fermented dry or semi-dry sausage" to reach pH 5.3.[9] The equation is $t_{max} = A/(T\text{-}15)$ where T is the maximum fermentation temperature (°C) and A is a coefficient equalizing 720 for fermentation temperatures between 24° and 32°C, and 560 and 500 for fermentation temperatures above 32°

and 40°C, respectively. Apparently, the use of this rule combined with the introduction of appropriate process controls and starter cultures significantly reduced the incidence of outbreaks of *S. aureus* food poisoning in the US due to the consumption of fermented "summer sausages."

The effect of various formulations and ripening conditions on *S. aureus* in unsmoked sausages fermented at temperatures common in Europe has been studied by Hechelmann et al.[74] If fermented at 23°C, a reduction in pH to 5.3 within 2 to 3 days also turned out to be critical in these products. This could be achieved by adding lactobacilli or *Pediococcus pentosaceus* as starters, with 0.3% of a rapidly fermentable sugar. It was also important to adjust the initial water activity to above 0.955, and to use ageing temperatures below 15°C until the water activity had decreased to below 0.90. At fermentation temperatures of 15°C, no growth of *S. aureus* was observed, irrespective of acid formation.

Listeria monocytogenes

Because of its wide distribution on meat and its ability to grow at low temperatures and relatively low water activity (>0.93), *Listeria monocytogenes* may be expected to be a hazard to the consumer of fermented sausage. However, there is no epidemiological evidence for the involvement of fermented sausages in outbreaks of listeriosis, and little if any growth was observed during sausage fermentation under conditions resembling commercial practice,[52] even in undried sausages[88,164] and in mold-ripened salamis.[17,78,153,184] Conditions controlling salmonellae and *S. aureus* were found also to prevent growth of listerias. However, to make sure that listerias do not grow on the surface of mold-ripened sausages, Rödel et al.[153] recommended lowering the ageing temperature for Italian-type salami to 8° to 10°C.

During sausage ripening, listerias die only slowly. The use of lactobacilli that form a listeriocidal bacteriocin as starters reduced the *Listeria* count early in fermentation by about 1 log.[14,56,78,164]

Spore-Forming Bacteria

Raw sausage mixtures may contain considerable numbers of *Bacillus* spores of which spices are a major source. Many *Bacillus* spp. show proteolysis and/or lipolysis in appropriate nutrient media. However, they fail to multiply and to cause spoilage during sausage fermentation, even if high numbers of facultatively anaerobic species and/or species capable of growing at low a_w are inoculated into raw sausage mixtures, and if faulty ripening conditions are used.[129] The authors concluded that *Bacillus* spp. are controlled in fermented sausages by a combination of low water activity, low pH, and absence of oxygen. The experience of manufacturers of fermented sausages in Germany also indicates no need to select spices with low numbers of *Bacillus* spores.

There is no practical or epidemiological evidence that clostridia may grow and form toxins during ripening and storage of fermented sausages. Botulinum toxin was only detectable if a sausage prepared with no glucose added was inoculated with about 10^4 spores of proteolytic strains of *Clostridium botulinum* per gram, heated to 58.3°C core temperature and subsequently kept at high temperature (27°C) for extended time in which the pH did not fall below 5.5.[23] This is far from any commercial practice. Growth and toxin formation by *C. botulinum* (proteolytic or nonproteolytic strains) is even less likely in "European-type" fermented sausages.[112,134] *C. botulinum* and other clostridia are controlled by the combination of pH and water activity in fermenting sausages, irrespective of nitrite addition, and do not represent a hazard for fermented sausages.

19.6.2 Control of Other Biological Hazards

Molds and Mycotoxins

Leistner and Eckardt[105] and Leistner[101] listed those mycotoxins that have been found on fermented sausages experimentally inoculated with toxigenic molds. Aflatoxins and other *Aspergillus* toxins were only found if such sausages were aged at elevated temperatures and relative humidities that are very unlikely to prevail in commercial practice.[2] If, as in normal practice, sausages are dried at temperatures of 15°C or below, toxinogenic aspergilli are outgrown by penicillia and *Scopulariopsis* spp.[81] Among the *Penicillium* toxins, small amounts of cyclopiazonic acid and verrucosidin and, possibly, citreoviridin and rugulosin may be formed in the outer layer of the sausage under these conditions.[105,161] Even though the levels found in experimentally inoculated sausages were small and restricted to no more than a few millimeters below the surface, growth of all undesirable molds on fermented sausages should be prevented, not only to eliminate the risk of mycotoxin and antibiotic formation, but also to avoid defects in appearance and flavor. The following preventive measures should be taken:

1. The surface of products to be mold ripened should be inoculated with a suitable nontoxic mold strain and the products dried at temperatures below 15°C.

2. On other fermented meats, mold growth may be inhibited by appropriate control of temperature and RH during ageing, and/or by surface treatment with smoke, permitted antifungal agents, or waxes. Antifungal smoke constituents as well as acetic and propionic acids are volatile and cannot safely prevent mold growth during extended storage. After fermentation, products may be dipped in solutions of antifungal agents such as potassium sorbate or natamycin (pimaricin). However, natamycin is an antibiotic that is also used in treatment of humans. Hence, its use for preservation of fermented sausage is restricted in many countries.
3. Packaged products to be stored at elevated temperatures for long periods (eg, snack sausages) should be dried to 22% moisture (corresponding to a water activity of 0.82 or less) and stored in the absence of oxygen. This results in the complete suppression of the growth of molds and a delay of rancidity.[183]

Viruses

The potential viral hazards in meats and the fate of viruses during meat processing have been reviewed by Cliver[24] and McKercher et al.,[120] respectively (see also Chapter 52). Viruses already present in livestock at the time of slaughter normally do not affect humans. Foot-and-mouth-disease virus is acid sensitive and likely to be inactivated during sausage fermentation.[47,138] The causative agents of African swine fever, swine vesicular disease, and hog cholera are inactivated only slowly during sausage ripening and are sometimes detectable even after 3 months. Therefore, fermented meats should, like unprocessed meats, not be exported from areas where these diseases prevail. There is no epidemiological evidence that fermented sausages are a major vector of viruses pathogenic for humans; however, enterovirus, echovirus, and poliovirus retain their infectivity during fermentation and drying of sausage. Hence, avoiding the handling of raw materials and fermented meats by hands contaminated by human feces is critical to prevent transmission of human pathogenic viruses via fermented sausages.

Parasites

Some parasites (eg, protozoa, nematodes, tapeworms) may escape detection during inspection of the animals and their meat at the slaughterhouse (see Chapter 51). Fortunately, they are inactivated by the low a_w values in dry sausages and dry hams. For example, *Toxoplasma* was rapidly inactivated during manufacture of fermented sausage,[173] and there is no epidemiological evidence of fermented meats being involved in the transmission of disease caused by protozoa. To inactivate 100–800 *Trichinella* larvae per gram fresh mixture, German-type sausages (eg, salami, cervelat, Teewurst) had to be ripened for 6 to 21 days and to attain a water activity (a_w) of 0.93–0.95. The low pH contributes to inactivation because in products of higher pH such as Genoa-type salami and raw hams, lower a_w values were required.[22,109] However, it is safe to state that fully dried meat products (a_w below 0.90) will not contain any viable protozoa or larvae of helminths, even if prepared from contaminated meat. If the presence of the larvae cannot be excluded by meat inspection, semi-dry and undried fermented sausages must be made from meat that has been stored frozen, or be heated to 58.3°C (137°F), as stipulated by US regulations.[9]

Biogenic Amines

Fermented foods may contain considerable amounts of amines, which may not only be precursors of nitrosamines but also elicit migraine or allergy-like symptoms in humans. Mean and median values of about 100 mg and maximum values of about 300 mg histamine kg^{-1} dry weight have been reported,[162,185,186,194] with a trend to higher levels in aged, mold-ripened products. Such levels, as well as the reported concentrations of other biogenic amines (eg, up to 1,000 mg kg^{-1} dry weight of tyramine) are unlikely to elicit scombroid-type poisoning or migraine-like symptoms in healthy individuals having normal activity of monoamino oxidase.[115] However, the published data also show that it is possible to produce high-quality fermented sausages with very low levels of biogenic amines. Hence, a better understanding of the factors affecting formation of biogenic amines during sausage fermentations is necessary.

The rate of amine formation is limited by the rate of protein degradation by tissue enzymes and, in particular in mold-ripened products, microbial enzymes.[48] Hence, more precursors (eg, peptides, amino acids) must be expected in meat stored for long time periods[185] or in mold-ripened products. Conditions enhancing the activity of acid-sensitive bacteria appear to increase the risk of biogenic amine formation.[118,162] By using good-quality, fresh raw material, appropriate starters, formulations and ripening conditions, formation of biogenic amines during sausage ripening may be minimized. Remarkably, certain strains of psychrotrophic lactic acid bacteria found on meat (eg, *Carnobacterium* spp.; strains of *L. curvatus*) are also capable of decarboxylating certain amino acids.[117,181] Hence, it is necessary to screen potential starter cultures for absence of the ability to decarboxylate amino acids.

There appears to be no formation of nitrosamines during meat fermentations,[97,133] even though the precursors (secondary amines and nitrite) may be present. However, severe heating at low a_w favors nitrosamine formation. Therefore, fermented meats should not be fried, and the residual levels of nitrite and nitrate should be minimized. There is no technological or microbiological reason for the addition of more than 150 mg sodium nitrite per kg to even the most unstable product (fresh, undried sausage), and excess nitrite is reduced to ammonia by the sausage microflora, usually leaving less than 10 mg $NaNO_2$ per kg of finished product.[192]

19.6.3 Risk Assessment

Using the information given in Section 19.6.1 and considering exposure to the agent, severity of the disease, and epidemiological data, the main risks to the consumer of fermented sausages are salmonellosis, infections caused by enterohemorrhagic *Escherichia coli,* and *Staphylococcus aureus* enterotoxicosis. Mycotoxins, viruses, parasites, and biogenic amines should not be forgotten, but risks to the consumer of fermented meats appear to be small, and preventive measures have already been discussed in Section 19.6.2.

19.6.4 Preventative Measures To Control Foodborne Pathogenic Bacteria

Figure 19-2 illustrates the main process steps critical for the control of growth of *Salmonella enteritica, Staphylococcus aureus,* and *Listeria monocytogenes* during sausage ripening, and the preventive measures to be taken. It is important to note that "lowering" of one "hurdle" may be compensated for by "fortifying" another hurdle.[102] For example, one may increase the initial water activity of the sausage mix within certain limits (as sometimes done for the manufacture of low-fat, low-sodium products) if the rate of acid formation is increased or the fermentation temperature lowered. This must be taken into account when setting up HACCP systems for the manufacture of fermented meats.

As long as there are no effective methods available to eliminate EHECs from livestock (particularly from cattle and lamb), the most important places for reducing EHEC contamination of the meat used for fermented sausage manufacture are during the skinning and evisceration of cattle and lamb. This is because at these stages, the risk of contamination of meat by fecal material is high. Accordingly, manufacturers of fermented sausages should take great care to buy their raw material from abattoirs with good hygienic practice. In addition, meat and meat products must not be touched by hands contaminated by human feces.

19.7 MECHANISMS AND CONTROL OF SPOILAGE OF MEATS DURING AND AFTER FERMENTATION
